1 EXECUTIVE SUMMARY

QIPC overview

Quantum Information Processing and Communication (QIPC) has the potential to revolutionize many areas of science and technology. It exploits fundamentally new modes of computation and communication, because it is based on the physical laws of quantum mechanics instead of classical physics. It holds the promise of immense computing power beyond the capabilities of any classical computer, it guarantees absolutely secure communication, and it is directly linked to emerging quantum technologies, such as, for example, quantum based sensors. The worldwide interest in the subject may be gauged by the recent significant increase of funding in quantum information technology; in particular

in the United States, Canada, Australia and in some countries in Asia (see section 2.2). Europe has played a leading role in the early development of QIPC, and, given appropriate research infrastructure and suitable funding, European researchers are well positioned to maintain Europe at the forefront of the field. However, this requires a significant effort at national level and a consolidation, coordination and unification of many national projects and initiatives under one common European umbrella with the lead of the research program of the European Commission. For Europe to remain competitive in this field in the future there is an urgent need for a substantial EU-programme in QIPC.

1.1 OVERVIEW OF QIPC RESEARCH AND ITS GOALS FOR THE COMING FIVE TO TEN YEARS

1.1.1 QUANTUM COMPUTING

From classical to quantum computing

Classical physics is at the root of present-day information processing: strings of bits (discrete digital states) are represented and processed in electronic devices (registers, logic gates etc.) through quantities such as charges, voltages, or currents. In Quantum Computing and more generally in Quantum Information Processing (QIP), one makes instead use of the laws of quantum mechanics replacing bits with qubits, two-state quantum systems that do not possess in general the definite values of 0 or 1 of classical bits, but rather are in a so-called 'coherent superposition' of the two. Full exploitation of this additional freedom implies that new processing devices (quantum registers, quantum logic gates etc.) need to be designed and implemented. As several sets of universal quantum gates acting on one and two qubits are known, a large scale quantum computer can in principle be built, provided the quantum physical system used meets some basic requirements (the so-called DiVincenzo criteria) on scalability, faithful initialization, manipulation, transmission and readout of qubits, and long coherence times with respect to the gate operation time.

these systems in view of scalability, coherence and speed of QIP, in particular also concerning their reliability, fault tolerance and use of error correction. Finally, development of a computer architecture must be complemented by interfacing with quantum communication to allow building of quantum networks.

Ultimately, the goal must be to transfer this academic knowledge about the control and measurement of quantum systems to industry. Major international companies have shown interest and support for developing and providing systems suitable for quantum manipulation.

From academy to industry

Few-qubit applications. A first short range goal is the realization of a few-qubit general purpose quantum computer including error correction, as a test bed for demonstrating operation of a quantum computer. In parallel, however, special effort must be made to further develop few qubit applications which range from quantum information processing and quantum communication all the way to quantum assisted precision measurements.

Short term goal I: test bed demonstrations

Many-qubit specialized applications. As a second short range goal, special purpose quantum computers with a large number of qubits should be developed. A highly relevant example is provided by quantum simulators, programmable quantum systems whose dynamics can be engineered such that it reproduces the dynamics of other many body quantum systems of interest, e.g., atoms in optical lattices simulating high temperature superconducting systems and/or quantum phase transitions. Full simulation of a quantum mechanical system consisting only of a few hundred particles (spins) requires in fact classical computing resources in terms of memory of the order of the number of atoms in the visible universe – clearly demonstrating the inadequacy of any classical computer for this task. Quantum simulators could be the first nontrivial applications of quantum information, providing answers to problems which are fundamentally beyond classical computing capacities, such as the study of microscopic properties of materials permitting free variation of system parameters, an accurate

Short term goal II: quantum simulators

Physical systems suitable for QIP

At present, a number of physical systems are under investigations for their suitability to implement a quantum computer. These include trapped ions and neutral atoms, cavity quantum electrodynamics (CQED), solid state devices (such as superconducting qubits, possibly in combination with circuit CQED, and spin qubits), all-optical devices, as well as impurity spins in solids, single molecular magnets etc.. During the last few years remarkable progress, measured in terms of the aforementioned DiVincenzo criteria, towards demonstrating the basic building blocks of a quantum computer have been reported in these systems. At present no fundamental physical roadblocks seem in sight for building a scalable quantum computer including error correction. However, a mixture of significant technological challenges and some open physical questions remain to be answered. At the same time it is premature to select a winner, rather research should progress on a broad front across all physical disciplines which studies

description of chemical compounds and reactions, or find out the reason why free quarks are not found in Nature.

Long term goal I: hybridization

Quantum interfaces. In the long term a first goal is the development of hybrid technologies and architectures for

quantum computation, including interfaces between them. This will stretch the theoretical and experimental resources of many branches of physics, from quantum optics and atomic physics to solid state devices. It is likely that there will not be a single winner in this search, but rather a number of different technologies complementing each other: some will be more suitable for quantum memories, some for quantum processing, and some for quantum communication and so on. Therefore, in addition to developing individual technologies, interfaces between the latter are also needed, so that different qubit 'memories' (atoms/ions, quantum-dots, squids) and carriers of quantum information (atoms/ions, photons, phonons, electrons) can be interconnected.

Long term goal II: fault tolerant computation

Fault-tolerant gates and architectures.

A second long range goal is the demonstration of fault-tolerant quantum

logic gates, by the engineering of sub-microscopic systems in which qubits affect each other in a controllable way, while avoiding at the same time undesired couplings with the environment leading to decoherence. Applying to quantum computers the traditional network model, simple quantum logic gates would be connected up into quantum networks. However, the more interacting qubits are involved, the harder it tends to be to engineer the interaction that would display the quantum behaviour, and the more components there are, the more likely it is that quantum information will spread outside the quantum computer and be lost into the environment, thus spoiling the computation. It has been proven that if decoherence-induced errors are small (and satisfy certain other achievable conditions), they can be corrected faster than they occur, even if the error correction machinery itself is error-prone. The requirements for the physical implementation of quantum fault tolerance are, however, very stringent, and can be met either by improving technology or by going beyond the network model of computation and designing new, inherently fault-tolerant, architectures for quantum computation. One candidate for such an alternative architecture, e.g., might be the one-way quantum computer model, in which errors can classically be fed-forward and corrected. At the end however, a fault-tolerant quantum computer will most likely be achieved by an optimized combination of both strategies.

The leading role of theory

Implementation theory. Theory must continue to play a leading role in guiding and supporting experimental

developments. Aside from finding and investigating fundamentally new algorithms especially suited for quantum computing, the various implementations require continuous theoretical work especially finding physical solutions where mere technology is yet too cumbersome. For example, operations in specially designed "decoherence free subspaces", i.e., physically tailored systems less susceptible to technical errors, will be an important feature in finding an optimum system and optimized algorithms. Therefore, the theoretical

work will have to cover a wide range of physical systems and technologies.

1.1.2 QUANTUM COMMUNICATION

Quantum Communication is the art of transferring quantum states from one place to another. The general idea is that quantum states encode quantum information: hence quantum communication also implies transmission of quantum information. Quantum Communication covers aspects of basic physics as well as of practical relevance. Additionally, it will take care of the whole "wiring" inside a quantum computer, i.e., contribute to the quantum interface. Already now, one of its outstanding results is the emerging technology of quantum cryptography, which promises absolute secure transmission of the key codes that are essential to encrypt messages with tamper proof security.

Quantum communication

More specifically, any encryption scheme entails the distribution of a secret key among legitimate users; as the key must be transmitted between sender and recipient, it is susceptible to interception by an eavesdropper. For a secret key made of classical bits, none of the two parties will ever know that their communication has been intercepted. Not so if the key is carried out by a quantum communication channel. As said before, qubits do not possess definite values such as the 0 or 1 of classical bits; rather, they represent a so-called coherent superposition of physical states (e.g., the polarizations of a photon). The laws of quantum mechanics imply that the mere act of observing a quantum bit modifies it, causing it to change its quantum state. The eavesdropper's attempt to intercept the secret key made of qubits will therefore be manifest to both parties. Quantum cryptography is now developing from the initial approach known as point-to-point Quantum Key Distribution (QKD), towards the management of quantum-based security over many-nodes networks, that are being built in various places worldwide (USA, Europe, Japan).

An example: quantum cryptography

Presently, technical problems are controlled well enough so that secure transmissions over a few tens of kilometers can be implemented. However, non-trivial problems emerge for really long-distance communication (hundreds to thousand of kilometers), and in the quest for higher bit rates. High-flux single photon sources as well as entangled photon sources should be developed in order to enhance the secure medium range quantum communication. At present photons are the only suitable system for medium-distance quantum communication, as they maintain a robust quantum state throughout transmission, can be detected efficiently and with low levels of noise (other systems, such as atoms or ions, can be used for building quantum memories but not to propagate qubits over long distances).

From short to medium- and long-range communications

But even light signals, whether viewed classically or quantum-mechanically, are dampened exponentially with distance in both optical fibres and free space. More fundamental basic research is needed in particular in production, detection and distribution of qubits. In classical optical telecommunications, this problem is solved by using simple devices known as repeaters, which amplify and

Repeaters: classical vs quantum

reshape the transmitted signal. But the latter are of no use for quantum communication: they are intrinsically noisy and create so many errors that any quantum key being transmitted would not survive. This is related to the fact that a classical repeater breaks down quantum entanglement, a purely quantum phenomenon associated with very strong, non-classical correlations between the states of two widely separated qubits. However, novel protocols (for instance based on entangled qudits) could enhance the fault-tolerance of quantum communication schemes and need further investigation. Entanglement is a crucial element in quantum communication schemes, which allows one to ‘teleport’ qubits directly to their destination, avoiding transmission losses. So quantum communication must reinvent the repeater concept, using quantum hardware that preserves entanglement.

Short term goal: making quantum communication an established technology

Real world medium-distance quantum communication. If Quantum Communication is to become, on the 5 to 10 year time-scale, an established technology, backing up the quantum

cryptography “boxes” which are already commercialized, several scientific as well as technological gaps have to be filled. In particular one needs to demonstrate the feasibility of ‘real world’ medium-distance quantum communication both in optical fibres and in free space, purely terrestrial and to and from flying quantum communication nodes, e.g., high altitude platforms (HAP) or satellite, and to increase the qubit transfer rate by several orders of magnitude. These two goals, together with the one of realizing long-distance secure quantum networks will be significantly advanced by developing quantum repeaters. Achieving these goals will require facing a number of non-trivial challenges, needing very strong interaction between fundamental and applied research.

Long term goal: global quantum communication

Quantum repeaters. In the long term a quantum repeater would actually be a small dedicated quantum processor, incorporating quantum memories, which,

whilst feasible, requires a significant effort and is perhaps the most important technological hurdle facing QIPC. So far we have seen some first experimental steps towards elements needed for a quantum repeater, but there is much work to be done. The basic elements to be developed are: medium range entanglement between memories, teleportation between different memories. The exact number of qubits that would have to be stored and processed in such a repeater to ensure high-fidelity quantum communication over thousands of kilometres is an open issue. But it is likely to be in the range of tens or hundreds – much lower than the number required for a fully fledged quantum computer. Therefore it is more likely that we will have secure global quantum communication before quantum code breaking.

1.1.3 QUANTUM INFORMATION SCIENCES – THEORY

Quantum Information sciences

Our conception of what a computation is has been altered drastically during history, since the times of Leibniz, Babbage and

Turing. The result of this remarkable history of ideas – computers as we know them today – has changed our modern society significantly. Yet, the development of

computing and communication devices has not come to a stop. Recent developments have shown, in fact, that we are at the beginning of a new era of harnessing the laws of nature, using quantum physics for unprecedented and very powerful ways of information processing.

Interdisciplinarity

The development of Quantum Information Science (QIS) has been driven by theoretical work of scientists working on the boundary between Physics, Computer Science, Mathematics, and Information Theory. In the early stages of this development, theoretical work has often been far ahead of experimental realization of these ideas. At the same time, theory has provided a number of proposals of how to implement basic ideas and concepts from quantum information in specific physical systems. These ideas are now forming the basis for successful experimental work in the laboratory, driving forward the development of tools that will in turn form the basis for all future technologies which employ, control and manipulate matter and radiation at the quantum level.

While the development of QIS has started as early as in the 80’s, the field has gained significant momentum in the last decade. Major triggers were the discovery of fast quantum algorithms and the identification of concrete physical systems in which a quantum computer could be realized. In the meantime, a broad spectrum of research activities can be observed, ranging from the study of fundamental concepts such as quantum entanglement, to novel applications such as quantum simulators, and with significant spin-off also to other fields of research.

In many of these activities, European research has played a leading role and has established a strong set of world leading centres. It is important to realize that theoretical activities are often interdisciplinary in nature and span a broad spectrum of research in which the different activities are benefiting from each other to a large degree. Thus it does not seem to be advisable to concentrate research on too narrowly defined topics only. The following list nevertheless tries to highlight the main current areas of quantum information theory as it has been described in more detail in the strategic report.

Main current areas of Quantum Information sciences

Quantum algorithms & complexity. Quantum algorithms will be one of the most powerful applications of quantum computers. We know only a few examples up to date, such as Shor’s factoring algorithm, but new techniques and protocols are currently being developed. This area remains one of the cornerstones of research in QIC.

Computational models & architectures. There are many different ideas of how to make quantum systems compute. New computer models, which have only recently been developed, are providing new agendas to formulate quantum algorithms. At the same time, they have opened new ideas for physical implementations of a quantum computer, and we expect new methods for fault-tolerant computation that will make it technologically less challenging to realize scalable devices in the laboratory.

Geometric and topological methods. These methods represent an alternative approach to the

realization of quantum computing. They have intrinsic fault-tolerant properties that do not need an active error detection and recovery; however, the overhead that one has to pay are longer operation times, so that much work must still be done to identify which of the available schemes suit better to quantum computation.

Quantum simulations. Quantum simulators may become the first short-term application of quantum computers, since with modest requirements one may be able to perform simulations which are impossible with classical computers. They could be used for a variety of purposes, e.g., to obtain an accurate description of chemical compounds and reactions, to gain deeper understanding of high temperature superconductivity, or to find out the reason why quarks are always confined.

Quantum error correction & purification. Despite its amazing power, a quantum computer will be a rather fragile device, susceptible to disturbances and errors. Fortunately, methods have been developed to protect such a device against disturbances and imperfections, as long as these are small enough. These methods are constantly being improved and refined, but there is still a lot of work to be done until we can run a quantum computer reliably.

Theory of entanglement. Entanglement represents a novel and particularly strong form of correlations which is not present in classical systems. It is a key resource in quantum information science and, at the same time, one of the most prominent features of quantum physics. Insights in the theory of entanglement will continue to have broad implications, and applications will lie not only within the field of QIS itself, but also in other areas of physics, such as field theory and condensed matter physics.

Multi-partite entanglement & applications. Research on multi-particle entanglement has emerged recently, and it is expected to have an impact on novel protocols for quantum information processing. Multi-partite entangled states represent key resources, both for quantum computers and for novel communication schemes with several users such as quantum-secret sharing, quantum voting etc. Alternatively one can consider multi-partite fingerprinting schemes that would allow for the determination of whether or not a number of databases are identical with very little resources.

Noisy communication channels. In practice, all communication channels such as optical fibres are subject to some level of noise. Such noise can destroy the crucial entanglement or other quantum properties

that are needed, e.g., for security or to reduce communication complexity. A proper understanding of how one can communicate via noisy quantum channels and of the capacities of such channels is at the heart of the study of quantum communication tasks.

Fundamental quantum mechanics and decoherence. Quantum information was born, in part, via research on the famous Einstein-Podolski-Rosen paradox and the issue of quantum non-locality. It is now understood that non-locality is one of the central

aspects of quantum mechanics. More generally, quantum information profits substantially from studying the fundamental aspects of quantum mechanics and, at the same time, it yields new perspectives, raising hopes of gaining a deeper understanding of the very basis of quantum mechanics. In particular, quantum information theory can provide deeper understanding of dynamics of open quantum systems.

Spin-off to other fields. A very exciting aspect of theoretical work in QIS is the impact that it is beginning to gain on other fields of science. Examples are given by the theory of classical computing, by field theory, and by condensed matter physics. Many of the questions that are now being asked in this area can only be answered or even formulated correctly because of the many insights and techniques gained in the research in entanglement theory in recent years.

Theoretical research in QIS in Europe has prospered through the efficient support for collaboration by the European Union, the European Science Foundation and the national funding bodies. In the face of significantly growing international competition from North America, Japan and Australia it will be essential that flexible support compatible with innovative work will continue to be provided.

1.1.4 SUMMARY OF SHORT- AND LONG-TERM GOALS

For convenience of synthesis, we summarize in a table a short list of objectives for the next and more distant future of quantum computing and quantum communication (the internal ordering of such lists does not necessarily reflect chronology). The great diversity and openness of the field of quantum information theory prevents from drawing a similar list for that particular subfield.

	Quantum Computing	Quantum Communication
5 years goals	Demonstrate: <ul style="list-style-type: none"> ▪ Devices realizing quantum algorithms with up to 10 qubits ▪ Fault tolerant computing and error correction on small scale systems ▪ Distributed quantum algorithm ▪ Different classes of entangled states up to 10 qubits ▪ Quantum simulation that cannot be simulated classically 	<ul style="list-style-type: none"> ▪ Build a quantum repeater with two nodes ▪ Interface photons with matter ▪ Secure quantum key distribution network

	Quantum Computing	Quantum Communication
10 years goals	<ul style="list-style-type: none"> ▪ Large dimension quantum memory ▪ Quantum algorithm with up to 50 qubits ▪ Quantum simulation of a key problem in science ▪ Quantum algorithm with fault tolerant error correction 	<ul style="list-style-type: none"> ▪ Satellite quantum communication ▪ 1000 km quantum cryptography ▪ Multi-node quantum networks ▪ Realization of new quantum protocols

1.1.5 SYNERGIES AND INTEGRATION

Towards integrated quantum systems

QIPC is a new conceptual framework, a new way of looking at things with deep reaching consequences from network security to understanding the structure of the physical reality. It covers a broad spectrum of activities, from researching the foundations of quantum mechanics between the microscopic and the macroscopic level, to the development of patented industrial applications like quantum key distribution devices. The three domains of QIPC, quantum computation, communication and theory, are all closely connected, and within these domains there are a variety of different approaches that are all striving towards the same goal - integrated quantum systems. This integration will provide the next great challenge and inspiration for QIPC. In recent years tremendous progress has been made in all three fields, improved distances and fidelities in quantum cryptography and teleportation, coherent control of atomic systems for processing and theory is making daily advances in developing a basis for the theory of quantum computer science. Characteristic of the work within QIPC is that proof-of-principle advances in each of the sub-domains are used when pursuing the work in the other sub-domains and this is a key issue for developing QIPC as an integrated science and the basis of future and emerging technology.

Different technologies for different components

The experimental demands on the next phase of QIPC research will have a larger focus on integration of components and their reliability as the field moves from research oriented problems to applied and even

commercial quantum technologies. Still an even closer interplay between theory and experiment will be needed in order to achieve complete realistic schemes for coherent manipulation and high-precision performance. These efforts will eventually lead to a pool of reliable technologies for the different components of a quantum architecture, much like it happens now for classical computers where magnetic, optical and electric bits are used for storage, transmission and processing of information, respectively. Clearly, it is too early to pick the winner implementation for the practical realization of a working quantum device: it is even possible that the best technology is still to be developed. The already ongoing integration among different research communities (for instance those working on solid-state and on atom/quantum optical systems) is a solid basis for further pushing these effort to integrating actual devices.

An avenue that theory needs to embrace in order for efficient

From theoretical to applied problems

implementations to be developed is a deeper understanding of entanglement, which is a quantum feature that permeates the whole QIPC; its complexity just started being appreciated and much is left to investigate both in terms of formal theoretical description and of its applications. One also needs to fully explore the potentials of the available physical systems in order to invent new communication protocols, to investigate algorithmic consequences of physical assumptions, and to develop new computational algorithms, both implementable with a small-scale quantum computer and exploiting the immense power entailed in quantum parallelism.

1.2 THE LEADING ROLE OF EUROPEAN RESEARCHERS IN QIPC

Europe as a leader in QIPC research

European researchers have been from the outset prominent in setting the agenda of, and leading, the worldwide research efforts in quantum information science, in friendly competition with similar efforts and programs in the US, Australia, Canada, Japan and China. This includes pioneering work on the foundations of the quantum theory of computation, quantum algorithms, and the discovery of entangled state quantum cryptography, which generated a spate of new research that established a vigorously active new area of physics, computer science and cryptology. Many subsequent

seminal contributions, inspired by the 1994 Shor's quantum factoring algorithm, such as ways of implementing quantum computation using ion traps, quantum dots, cavity QED, optical lattices and a number of other technologies, novel computational architectures, methods of error correction and fault tolerant quantum computation originated in Europe. A unique feature and strength of European research is the broad range of activities and expertise, linking coherently efforts from experimental realization all the way to basic theoretical questions in quantum information science and quantum physics.

1.3 RECOMMENDATIONS FOR FUNDING ON THE EU AND NATIONAL LEVEL

QIPC has established itself as one of the key new multidisciplinary fields between theoretical and experimental physics, computer science and mathematics. Continued competitiveness of the EU and its member nations requires a significant effort both on the European and national level

- **QIPC must take a prominent and established position in EU research efforts**, e.g., in the Seventh Framework Programme for Research of the European Commission (FP 7), and find its counterpart in national programs.
- **The structure of the funding** must account for the interdisciplinary character of the field, and must support a spectrum of activities across different disciplines from experimental to theoretical physics, computer sciences and mathematics.
- **Links with industry** must be developed, both on the level of possible commercial exploitation, and in research programs making new technologies available, outside the capabilities and know-how of traditional QIPC basic-research oriented laboratories. In particular, links with micro- and nano-fabrication facilities and related technology centers must be strengthened, and QIPC spin-off new quantum technologies like quantum sensors and high precision measurement devices ought to be encouraged.

2. INTRODUCTION: THE MAJOR VISIONS AND GOALS OF QIPC

Classical information is not longer enough

The theory of classical computation was laid down in the 1930s, was implemented within a decade, became commercial within another decade, and dominated the world's economy half a century later. However, the classical theory of computation is fundamentally inadequate. It cannot describe information processing in quantum systems such as atoms or molecules. Yet logic gates and wires are becoming smaller and soon they will be made out of only a handful of atoms. If this process is to continue in the future, new, quantum technology must replace or supplement what we have now.

Quantum information goes beyond it

In addition, quantum information technology can support entirely new modes of information processing based on quantum principles. Its eventual impact may be as great as or greater than that of its classical predecessor.

Quantum bits and superposition

While conventional computers perform calculations on fundamental pieces of information called bits, which can take the values 0 or 1, quantum computers use objects called quantum bits, or qubits, which can represent both 0 and 1 at the same time. This phenomenon is called quantum superposition. Such inherently quantum states can be prepared using, for example, electronic states of an atom, polarized states of a single photon, spin states of an atomic nucleus, electro-dynamical states of a superconducting circuit, and many other physical systems. Similarly, registers made out of several qubits can simultaneously represent many numbers in quantum superpositions.

Quantum parallelism

Quantum processors can then evolve initial superpositions of encoded numbers into different superpositions. During such an evolution, each number in the superposition is affected and the result is a massive parallel computation performed in a single component of quantum hardware. The laws of quantum mechanics then allow this information to be recombined in certain ways. For instance, quantum algorithms can turn a certain class of hard mathematical problems into easy ones – the factoring of large numbers being the most striking example so far. Another potential use is code-breaking, which has generated a great deal of interest among cryptologists and the data security industry.

The power of quantum computation

In order to accomplish any of the above tasks, any classical computer has to repeat the same computation that many times or use that many discrete processors working in parallel. This has a decisive impact on the execution time and memory requirement. Thus quantum computer technology will be able to perform tasks utterly intractable on any conceivable non-quantum hardware.

Entanglement: a new resource

Qubits can also become entangled. Quantum entanglement is a subtle non-local correlation between the parts of a quantum system. It has no classical analogue. An entangled state shared by two separated parties is a valuable resource for novel quantum communication protocols, including quantum cryptography, quantum teleportation and quantum dense coding.

Quantum cryptography offers new methods of secure communication that are not threatened even by the power of quantum computers. Unlike all classical cryptography it relies on the laws of physics rather than on ensuring that successful eavesdropping would require excessive computational effort. Moreover, it is practical with current quantum technology - pilot applications are already commercially available.

Quantum continuous variables

While the central concepts of quantum information sciences have initially been developed for qubits, the alternative possibility to realize quantum informational and computational tasks using continuous variables has been investigated more recently. The use of quantum information carriers that have a continuous spectrum, such as the quadrature amplitudes of the quantized light field, has several potential advantages over qubit-based processes. Such advantages lie in the prospect for higher optical data rates and simpler processing tools, based upon standard telecommunication techniques. Another significant strength of this paradigm is that the light-atoms quantum interface can be designed for continuous variables, so that atomic continuous-variable systems can be used as a memory for light.

Challenges at the quantum level

Experimental and theoretical research in quantum information science is attracting increasing attention from both academic researchers and industry worldwide. The knowledge that nature can be coherently controlled and manipulated at the quantum level is both a powerful stimulus and one of the greatest challenges facing experimental physics. Going to the moon is straightforward by comparison – though fortunately the exploration of quantum technology has many staging posts along the way, each of which will yield scientifically and technologically useful results.

Building quantum hardware

In principle we know how to build a quantum computer: we start with simple quantum logic gates and connect them up into quantum networks. A quantum logic gate, like classical gates such as AND and OR, is a very simple computing device that performs one elementary quantum operation, usually on one or two qubits, in a given time. However, the more interacting qubits are involved, the harder it tends to be to engineer the interaction that would display the quantum behaviour. The more components there are, the more likely it is that quantum information will spread outside the quantum computer and be lost into the environment, thus spoiling the computation. This process is called decoherence. Thus the task is to engineer sub-microscopic systems in which qubits affect each other but not the environment. The good news is that it has been proved that if decoherence-induced errors are small (and satisfies certain other achievable conditions), they can be corrected faster than they occur, even if the error correction machinery itself is error-prone. The requirements for the physical implementation of quantum fault tolerance are, however, very stringent. We can either try to meet them

directly by improving technology or go beyond the network model of computation and design new, inherently fault-tolerant, architectures for quantum computation. Both approaches are being pursued.

Harnessing decoherence in quantum communications

There are many useful tasks, such as quantum communication or cryptography, which involve only a few consecutive quantum computational steps. In such cases, the unwelcome effects of decoherence can be adequately diminished by improving technology and communication protocols. Here the research focus is on new photon sources, quantum repeaters and new detectors, which will allow long-distance entanglement manipulation and

Satellite global quantum communications

communication at high bit rates, both in optical fibers and free space.

Within a decade, it will be possible to place sources of entangled photons on satellites, which will allow global quantum communication, teleportation and perfectly secure cryptography. Quantum cryptography relies on quantum communication technology but its progress and future impact on secure communication will depend on new protocols such as, for example, quantum-cryptographic authentication and quantum digital signatures.

Quantum simulators...

The next thing on the horizon is a quantum simulator. This is a quantum system in which the interactions between the particles could be engineered to simulate another complex system in an efficient way – a task that is inherently intractable on classical, but not quantum, technology.

...and their real-life applications

Building quantum simulators would allow, for example, the development of new materials, accurate description of chemical compounds and reactions, or a deeper understanding of high temperature superconductivity. The goal is to push the existing quantum technologies, such as optical lattices, to their limits and build quantum simulators within a decade or so.

Scalable quantum technologies

Last but not least, the search for scalable quantum information technologies goes on. This astonishing field appears to involve practically the whole of physics, and stretches the theoretical and experimental resources of every branch of physics, from quantum optics and atomic physics to solid state devices. It is likely that there will not be a single winner in this search: a number of different technologies will complement each other. Some of them will be more suitable for quantum memories, some of them for quantum processing, some for quantum communication and so on. Therefore, in addition to developing individual technologies, we also need interfaces between these technologies, so that we can transfer a qubit, for example, from a polarized photon to an electron in a quantum dot. The hybrid technologies and architectures for quantum computation, including interfaces between them, are the long-term goals for years to come.

A new way of harnessing Nature

Quantum information technology is a fundamentally new way of harnessing Nature and it has potential for truly revolutionary innovation. There is almost daily progress in developing promising technologies for realising quantum information processing with various advantages over its classical counterparts. After all, the

best way to predict the future is to create it. From the perspective of the future, it may well be that the real computer age has not yet even begun.

3. DIFFERENT ASPECTS OF QIPC RESEARCH IN EUROPE

Quantum Information Processing and Communication (QIPC) is a vigorously active cross-disciplinary field drawing upon theoretical and experimental physics, computer science, engineering, mathematics, and

material science. Its scope ranges from fundamental issues in quantum physics to prospective commercial exploitation by the computing and communications industries.

3.1 QIPC RESEARCH IN EUROPE – EUROPEAN UNION LEVEL

Role of the FET unit for QIPC

QIPC has a high-risk nature and long-term outlook with visions within the scope of information and communication technologies. The potential of QIPC was quickly recognized by FET – the Future and Emerging Technologies part of the Information Society Technologies priority of the Research Programme of the European Commission. FET has been very successful in attracting to the IST Program the best research teams in Europe, which are also among the best ones in the world. The pathfinder role of FET plays a crucial role for the development of QIPC in Europe.

Precursors of the QIPC Proactive Initiative

In the late 80's and early 90's quantum phenomena were studied by projects funded by the EC in the field of optoelectronics and electronics with the aim to overcome the limitations to the respective state-of-the-art devices. In the Fourth Framework Programme (FP4, 1995 – 1998) this research gradually evolved towards the objective of “quantum information processing”. The focus was on the demonstration of quantum entanglement with photons, which was technologically more mature. In the mid 90's, important results were achieved by several groups in Europe and shortly after they became the driving force behind a number of FET projects.

The QCEEP Pathfinder Project

During 1998 the QCEPP working group (the so-called Pathfinder Project) laid the bases for the research field of QIPC at European level and was the first endeavour explicitly addressing this area of research. This working group produced an extensive report with a roadmap, a map of European research teams with relevant competencies and set the research agenda for several years ahead. It played a crucial role by organizing the research community, by stimulating it to reach critical mass within a short time period and by building the support for the launch of QIPC as a Proactive Initiative.

QIPC Proactive Initiative: FP5

In FP5 (1999–2002) FET launched QIPC as a Proactive Initiative (PI). It was implemented via ‘calls for proposals’ directly targeted to QIPC and a certain amount of the FET budget was reserved in advance. There were two calls for proposals and 25 projects were launched with total cost of 41 M€ and EU funding of 31 M€. The contracts of the last group of FP5 projects finish at the end of 2005. Integrate the projects arising from the Open scheme with those supported through the proactive initiative and coordinate the work of all these projects was a main priority of the proactive initiative in FP5. Important traditions were also established at that time. Each year since the beginning of the proactive initiative two major events are organized. The first one is a ‘cluster review’ and conference. Its goals are to evaluate the work of each project and how its objectives

fit within the cluster, to revise priorities if necessary and to evaluate the progress of the cluster as a whole. The second event is the annual European QIPC workshop where projects present their work. Both forums give the opportunity for interactions between the members of the projects and for cross-fertilization.

In FP6 (2003–2006) QIPC continues as a FET PI. There was one call for Integrated Projects (IP) with deadline 22 September 2004. Three Integrated Projects succeeded in the evaluations and started in November 2005 with a contract for four years and total EU funding of 25 M€:

QIPC Proactive Initiative: FP6

SCALA – Scalable Quantum Computing with Light and Atoms (9.4 M€): The focus is on the realization of a scalable quantum computer, by using individually controlled atoms, ions and photons. This long-term goal is divided into two specific objectives, achievable during the project duration: A) the realization of interconnected quantum gates and quantum wiring elements. B) the realization of first approaches of “operational” quantum computing, which include (i) systems able to perform small-scale quantum algorithms, such as error correction (ii) special-purpose quantum processors, such as quantum simulators, and (iii) entanglement-assisted metrology.

QAP – Qubit Applications (9.9 M€): The focus is on qubit applications that are based on photonic, atomic and solid state systems. One of the project objectives is to design, build and operate quantum memories. It also aims to developing scalable quantum networks and operational prototypes of quantum repeaters that would allow to transmit quantum entanglement over large distances (both in fiber and free space). The ultimate goal is to design prototypes for satellite communications based on quantum entanglement. The project also strives to developing operational demonstrations of efficient control of dynamics of few-qubit quantum systems that will be employed for performing quantum simulations.

EuroSQIP – European Superconducting Quantum Information Processor (6M€): The focus is to develop a 3-5-qubit quantum information processor capable to: - run elementary algorithms; demonstrate quantum state control of a macroscopic multi-partite system; demonstrate entanglement and entanglement transfer; provide storage of quantum information; provide quantum communication interfaces; run simple quantum error correction schemes for suppression of decoherence. This will be implemented on platforms based on Josephson junction technology for i) charge-phase and ii) flux qubits. .

The IPs proposed research goes obviously beyond the present state-of-the-art, which confirms the strong

European presence in QIPC and the progress made in the last years. All projects deal with central topics of quantum computing and one of them (QAP) addresses in addition central topics of quantum communication and quantum information. All three consortia involve leading European scientists in their respective fields. In all projects the European dimension is a clear added value. In two of them (SCALA and QAP) the accent on integration across different disciplines and approaches is very strong and it is considered crucial for the further advancement of QIPC in Europe.

QIPC in FET-Open:
FP5 and FP6

QIPC is also funded via the FET-Open continuous submission scheme, which supports long-term, risky and visionary research. In this case the research area is not specified in advance and QIPC projects are competing with all other areas sponsored by FET. The role of FET Open is essential, for it supports new topics that had not been addressed in the proactive initiative and allows filling the time gap between dedicated QIPC calls. In FP5 ten QIPC projects with total cost of 7 M€ and EU funding of 5.6 M€ were launched. The QUIPROCONE Thematic Network successfully coordinated all QIPC projects in FP5, integrating the projects arising from the Open scheme with those supported through the proactive initiative. In FP6, eight smaller projects (Specific Targeted Research Projects, or STREPs) were contracted via FET Open for a total EU funding of 13.6M€: COVAQIAL - Continuous Variable Quantum Information with Atoms and Light, QUELE - Quantum Computing with Trapped Electrons, RSFQUBIT - RSFQ Control of Josephson Junctions Qubits, OLAQUI - Optical lattices and quantum information, ACDET - Acoustoelectronic single photon detector, MICROTRAP - Development of pan-European micro-trap technology capability for trapped ion quantum information science, QICS - Foundational Structures of Quantum Information and Computation, EQUIND - Engineered Quantum Information in Nanostructured Diamond.

QIPC Coordination
Actions

At the end of 2006 there are two active Coordination Action Projects. These are not research projects, but rather their goal is to collaborate with the QIPC FET proactive initiative in developing a strategy and in carrying out common activities.

ERA-Pilot QIST – *Structuring the ERA with quantum information science and technology* (850 k€): Its goal is to promote QIPC research in Europe and to give recommendations to European and national authorities on policy, structuring, coordination and funding. Its work includes: contribute to the updates of the QIPC Roadmap; develop a map of European QIPC groups and their expertise; develop a QIPC classification scheme according to the roadmap; compile information about national and international QIPC programmes. The contract is extended till the end of 2007 and cooperation with the QUROPE coordination action described below is established.

QUROPE – *QIPC in Europe* (1 M€): It aims at structuring the European QIPC research community around the FET QIPC proactive initiative and covers a large spectrum of activities like: develop a common European vision, strategy and goals for QIPC research by taking over the ERA-Pilot tasks of developing and updating the QIPC roadmap, increase the public visibility and aim at broad

dissemination activities; develop and support an Electronic Information Infrastructure and Information Exchange (with a feedback channel); organize scientific meetings; create links with industry; develop international collaboration outside of Europe. It is important to note that the consortium consists of 34 research groups, among the best from all over Europe. These play the role of regional focal points for other 43 research groups who are defined as affiliated members. In this way a considerable part of the scientific community can participate in the actions undertaken by the project. The decision making process is in the power of the Governing Board which consists of 19 well known scientists. Therefore the project is central to the entire QIPC scientific community and plays the role of its collective representative. It has reached a higher level of maturity and integration than all other similar actions in the past.

In order to complete the picture of the projects in the area of QIPC funded by the European Commission, it is necessary to mention that there is one project in the field of QIPC which is not funded by FET but rather by the Security strategic objective of the IST Research Program. It is called SECOQC - Development of a Global Network for Secure Communication based on Quantum Cryptography. This FP6 IP started on April 2004, and it will last four years with a total cost of 16.82 M€ and EU funding of 11.35 M€. The project emerged naturally from the FP5 FET QIPC projects in the field of applied quantum cryptography. The consortium comprises 40 research groups which are the best ones in Europe in this field. They have all been or still are partners in the FET QIPC projects and are active participants in the actions undertaken by the QIPC proactive initiative. SECOQC has very ambitious goals in the practical realizations of quantum cryptography: specify, design, and validate the feasibility of an open, Quantum Key Distribution infrastructure dedicated to secure quantum communication, as well as fully develop the basic enabling technology. A network will be designed for dependable and secure long-range quantum communication building upon a Quantum Key Distribution (QKD) technology. The functionality of the developed architecture will be demonstrated. The design will be based on a comprehensive analysis of requirements of potential users. In January 2007 the SECOQC project consortium published a White Paper on Quantum Key Distribution and Quantum Cryptography.

Other projects in the area of QIPC funded by the European Commission research program in general are the existing two Marie Curie research training networks funded by the Marie Curie program of DG RTD. They are CONQUEST: Controlled Quantum Coherence and Entanglement is Sets of Trapped Particles and ATOMCHIPS.

The FET QIPC proactive initiative fulfils a natural leading role and is the focal point for all QIPC researchers in Europe. Its main objectives can be divided into two groups. The first one is quite obvious: define calls for proposals, organize evaluations of proposals, negotiate project contracts, manage and monitor projects throughout their complete lifetime. The second

SECOQC

Marie Curie RTNs

Objectives of the FET
QIPC Proactive
Initiative

group is less evident and much more sophisticated. But most importantly, in order to have any chances of success, it has to be carried out every step of the way in close collaboration with the entire research community and with its active participation. Bottom-up approach, exchange of ideas and an open dialogue, mutual respect and common understanding, comprehensive and no-nonsense feedback channels are all key elements of this very difficult but stimulating and rewarding journey. Some of the objectives in the second group are:

- Promote information exchange and collaboration between research groups and projects
- Plan pan-European events and activities
- Maintain pan-European dissemination activities and a comprehensive public image of the field
- Create and maintain a dialogue with the research management in member states and at European level
- Coordinate efforts between national and local programs on one hand and the EU initiative on the other hand
- Structure and strengthen the research community, unify it around the QIPC initiative
- Create a sense of community and a common European identity, develop a pan-European strategy for the future development of the community
- Develop and maintain an European QIPC web portal with a comprehensive feedback channel
- Define a common vision and objectives for research, a pan-European strategy for research and therefore continuously maintain and update the European QIPC roadmap
- Support emerging new areas, research topics and applications
- Create international alliances and a common strategy for international collaboration at pan-European level
- Maintain a dialogue and create a common strategy to attract industrial partners
- Create and maintain a common strategy and unified standards for the education of young researchers
- Maintain a global overview at European level

All these elements need to be in dynamic equilibrium between each other and it is very important to respond on time and proactively to:

- the changing needs of the community
- the fast research developments
- changes at EU and Commission level
- changes in the international scene

Results of the FET QIPC Proactive Initiative

The QIPC proactive initiative has significantly enhanced the European Research Area in the field in terms of fostering greater integration between

previously disjoint research groups and national programs. It is an excellent example that the whole is worth much more than its individual parts. The proactive initiative has become the focal point for all research teams in Europe and for all major activities in the field.

An important sense of community and a common European identity among scientists are in the process of development. A common European research strategy has been elaborated in the QIPC roadmap. All these activities have naturally led to a greater awareness and prominence of QIPC research in Europe. It is now a well established scientific field which has matured in the last ten years. There is critical mass in Europe in the main sub-fields and European science is competitive at world level. Some applications are already fit for real-world deployment. The FET QIPC proactive initiative is thus a very strong and successful unifying and structuring factor, which allowed the European groups to be at the forefront of research in a very competitive international environment and in a very fast developing field which is at the cutting edge of science in general. It is clear that QIPC research has gained an important European dimension which is crucial for its future.

Considering all these developments, it is therefore necessary to substantially expand and strengthen activities at European level in order to be able to exploit the full potential of European research and to withstand the challenges of the international competition. In particular there is a need for increasing the QIPC funding at the European level. Funding must carefully balance between focusing on specific promising areas and topics, while being open towards a whole spectrum of existing research fields and the possibility of new ones opening up. It is in fact too early to pick the winner implementation for the practical realization of a general purpose quantum computer and it is possible that the concrete technology is still to be developed. At this stage we need to keep a diversity of different approaches and funding needs in order to increase the probability of success and to ensure continuity. FET has attempted to provide continuous funding for solutions which proved promising while at the same time encouraging new ideas. The need for continuity and increase of funding necessitates commitment from the funding agencies and the active collaboration of researchers to position QIPC research in a larger strategic and political context.

Need for a carefully planned funding

Other actions that will help in achieving the ambitious goal of making QIPC a reality, would be

Other actions needed

- expand activities to support the main objectives of the QIPC proactive initiative as given above
- support and maintain research in all the main sub-domains of QIPC: quantum communication, computation and information theory
- keep a diversity of experimental realizations and approaches, and yet actively to look for synergies and integration between them in order to reach concrete objectives
- ensure timely and appropriate concentration of efforts and coordination of activities

Breakthroughs of the type needed to make QIPC a reality cannot be expected to follow a precise timetable. It is however imperative that at each point in time we have a clear understanding of the results obtained, an assessment of the strengths and weaknesses in present research, as well as a clear definition of the challenges and the objectives.

3.2 QIPC RESEARCH IN EUROPE – NATIONAL LEVEL

Different QIPC funding organizations

Apart from the EU program, QIPC is also coordinated and funded by several organisations at the national or regional level. All groups involved in QIPC receive support from their home institutions (e.g. universities) in form of building costs, salaries, etc. This basic support is difficult to quantify precisely, for most of the time it is impossible to know the exact costs, and some estimation (e.g. based on the size of the group under scrutiny) would be needed. In terms of external funding, one can distinguish several levels.

- The main funding source for QIST programs usually comes from a few national organisations in each country, mainly ministries, government agencies, or Academies of Science.
- Sometimes local funding comes from regions or cities that wish to attract centers of excellence in QIST.
- Other sources of funding are emerging, in particular the ones based on start-ups and agencies such as the European Space Agency.
- Some groups also have grants from American funding agencies, such as DARPA, ARO, and NIST.

3.2.1 NATIONAL FUNDING

QIPC National initiatives

As a basic research field, QIST is still traditionally funded by the different national governmental organisation depending on the country (ministry, governmental agency etc.). These agencies fund every research topics and QIST is typically a small percentage of the overall budget (in the percent range). However many of them have recently developed focus program or umbrella topics for QIST.

The identified main national founders for each country are the following

- **Austria**
 - Austrian Federal Ministry of Transport, Innovation and Technology (BMVIT)
 - Austrian Research Promotion Agency (FFG)
 - Zentrum für Innovation und Technologie GmbH
 - City of Vienna
 - Austrian Science Fund (FWF)
 - Tiroler Zukunftsstiftung
- **Belgium**
 - Fund for Scientific Research - Flanders/Belgium (FWO)
 - Fondation National de la Recherche Scientifique (FNRS)
 - Communauté Française de Belgique
 - Belgian Federal Science Policy Office

- **Bulgaria**
 - Ministry of Education and Science
 - National Science Fund.
- **Czech Republic**
 - Ministry of Education
 - Czech Science Foundation
 - Förderagentur der Republik Tschechien (GACR)
 - Förderagentur der Akademie der Wissenschaften (AVCR)
 - Ministry of Defense, Ministry of Interior
- **Cyprus**
 - Research Promotion Foundation (RPF)
- **Denmark**
 - Danish National Research Foundation (DG)
 - Ministry of Science Technology and Innovation
 - Strategic Research Centre for Nano Science
 - Danish Research Agency (FORSK)
 - Danish Agency for Science, Technology and Innovation (FIST)
- **Estonia**
 - Estonian Science Foundation (EstSF)
 - Ministry of Education and Research
 - Ministry of Economics Affairs and Communication
 - EE Enterprise Estonia
- **Finland**
 - Academy of Finland
 - National Technology Agency of Finland (TEKES).
- **France:**
 - Agence Nationale pour la Recherche (ANR)
 - Région Ile de France (Paris area), which supports QIST trough two main channels :
 - Institut Francilien de Recherche sur les Atomes Froids (IFRAF), <http://213.251.135.217/ifraf/>
 - Centre de compétence NanoSciences Ile de france (C'NANO). <http://www.cnanoidf.org/>
 - Région Rhone-Alpe
 - Centre National de la recherche Scientifique (CNRS)
 - Ministère de la Recherche
 - Délégation Générale pour l'amement (DGA)
 - Direction de la Recherche Technologique
 - ANVAR (L'agence francaise de l'innovation)
 - Ministère de l'Économie des Finances et de l'Industrie.

- **Germany**
 - Deutsche Forschungsgemeinschaft (DFG)
 - Bayerisches Staatsministerium
 - Landesstiftung BW
 - Max-Planck-Society
 - VDI Technologiezentrum GmbH
- **Greece**
 - Ministry of Development
 - General Secretariat for Research and Technology (GSRT)
- **Hungary**
 - Ministry of Education
 - Hungarian Scientific Research Fund
 - Hungarian Academy of Science
 - National Office for Research and Technology (NKTH)
- **Ireland**
 - Advisory Science Council (ASC)
 - Science Foundation of Ireland (SFI)
- **Italy**
 - Italian National Research Council (CNR)
 - Ministry for Education and Research (MIUR)
 - Istituto Nazionale di Fisica Nucleare (INFN)
 - Istituto Nazionale di Alta Matematica (INDAM)
 - Istituto Nazionale di Ricerca Metrologica (INRiM)
 - Regione Piemonte
 - San Paolo Foundation
 - Nanotechnology lab
 - QIPC is also one of the two scientific lines that CNISM (Consorzio Interuniversitario per le Scienze Fisiche della Materia) decided to support
- **Luxembourg**
 - Fonds National de la Recherche
- **Netherlands**
 - Foundation for Fundamental Research on Matter (FOM)
 - Netherlands Organization for Scientific Research
 - The Technology Foundation (STW)
- **Poland**
 - Ministry of Science and Higher Education
 - Ministry of Science and Information Technology
 - Polish Academy of Sciences
- **Portugal**
 - Science and Technology Foundation (FCT)
 - Innovation Agency (AdI)
- **Russia**
 - Russian Foundation for Basic Research
- **Slovakia**
 - Research and Development Support Agency (APVV)
 - Quantum Information program of the Slovakian Academy of Science.
- **Spain**
 - Ministry of Education and Science (MEC)
 - Ministry of Science and Technology (MCT)
 - University of Barcelona
 - Generalitat de Catalunya
 - Madrid General Government
- **Sweden**
 - Knowledge Foundation
 - Swedish Foundation for Strategic research (SSF) via the QIP consortium (Chalmers, Göteborg, and KTH, Stockholm)
 - Swedish Research Council (VR) – Natural and Engineering Sciences
 - Swedish foundation for International Cooperation
 - The Swedish Royal Academy of Science
- **Switzerland**
 - Swiss National science Foundation (SNF).
- **Turkey**
 - Tubitak-Uekae
- **United Kingdom**
 - Royal Society
 - Research Council
 - DTI Department of Trade and Industry
 - Engineering and Physical Sciences Research council (EPSRC)
 - Defence Science and Technology Laboratory (DSTL)

3.2.2 LOCAL FUNDING

As a highly promising field, QIST is often supported at the local level (city or region). Several examples in Europe have led to the creation of centers for Quantum Information, sometimes in a more general context. This funding can be quite stable in time, and usually consists in particular of a large startup sum, but also in a more long-term support. One can cite for instance:

QIPC Regional initiatives

- The region of Catalonia in Spain strongly supported the creation of the Institute for Photonic Science (ICFO) in 2002 in Barcelona, which has a strong emphasis on QIST. This institute is meant to be permanent and, when at full size, will employ up to 300 people.
- The Region of Tyrol and the city of Innsbruck in Austria also supported the creation of the Institute for Quantum Optics and Quantum Information (IQOQI); this centre was mentioned as “an example of outstanding quality” for activity in atomic molecular and optical physics research in a recent report of the US National Research Council.
- The Region Paris-Ile-de-France through the creation of the Francilian Institute for Research

on Cold Atoms (IFRAF), which comprises more than 30 groups from 6 different laboratories in Greater Paris.

- The United Kingdom is funding an Interdisciplinary Research Collaboration (IRC) in QIPC between leading research universities and industrial laboratories. The initiative started in April 2004 with a funding level of 15M€ in four years.

These initiatives can either, as for ICFO, create a new centre of excellence, or as in the case of IFRAF, construct a new centre of excellence from an existing pool of competence. In most cases the local funding is motivated by the development of a high-impact scientific field and high-level research, and it has a beneficial impact on local industry and economy.

3.2.3 OTHER FUNDING

As possible applications of QIST become likely to appear in the near future, start-ups have begun to emerge. The main interest so far is in quantum cryptography, in particular Quantum Key Distribution.

QIPC in industries and spin-off

The oldest European company is IdQuantique, spin-off from the university of Geneva in 2001. Several new appeared recently: SmartQuantum, created in 2004 in Lagnon, France, Qutools in Munich, Germany. Other competing start-ups for early adopters on the market are MagiQ, Optemax, and Qinetiq from the USA. These companies are mostly spin-off of QIST research groups, funded through the usual start-up scheme: university incubators at the early stage of their existence, then business angels or hedge funds to sustain them beyond their first years of existence. They mainly develop commercial fibered QKD systems, but most of them admit that there is no real market for such system yet. There is however already a small but active market for Quantum-based Random Number Generators (IdQuantique).

Quantum computing has also aroused interest for possible commercial applications. However the investment required and the timescale for developing a commercial quantum computer are much larger than for a QKD system. There is no start-up interested in developing a quantum computer in Europe so far, the only example known being in Canada, where one company (D-WAVE) has been created in 1999.

Several very large companies have also interest in QIST, with a focus on applied system research and components. In Europe, the main companies involved are Toshiba (UK), Thalès (France), France Telecom (France), Philips (Netherlands), Pirelli (Italy), Hitachi (UK) Hewlett-Packard (UK). Worldwide, companies such as IBM and NEC are also involved in QIST. The companies either have their own lab (Toshiba, HP, IBM), and/or can alternatively fund research groups (Philips). It has proven practically impossible to obtain reliable information about the amount of investment in QIST by these companies.

Another interesting source of funding is the European Space Agency (ESA). Several 50k€ feasibility studies on Quantum Communication in space were successfully completed since 2002 and one experimental terrestrial 200k € study over 144 km horizontal free-space link is ongoing. Within ESA's science program, the proposal Space-QUEST (to place a QKD terminal onboard the International Space Station) was rated as 'outstanding'. Several European industries submitted proposals to develop a prototype engineering model of a faint laser and entangled photon source with a total budget of 600k €. In the second half of 2008 a study on the feasibility of a QKD system on various future satellite missions is expected with 300k€. So far more than 1Mio€ have been spent on the different studies under evaluation at the time this report was made. But the overall budget for the Space-QUEST project, if it is accepted, would be approximately 80M€ until 2014, with approximately 20% devoted to basic research. If successful, this would make ESA a major funding source for QIST in Europe.

3.3 QIPC RESEARCH IN THE INTERNATIONAL CONTEXT

QIPC's own identity as a research field

Quantum information processing has become a scientific discipline with its own identity during the last ten years. The advent of quantum cryptography in the 80s and then the recognition of quantum computing in the 90s, for example using Shor's algorithm, provided the motivation and have been the starting point of serious experimental and theoretical efforts to realize QIPC at large.

Europe at the leading edge of QIPC research

Through the activities of the 2000-2004 EC FP5 FET-PI QIPC programme, Europe has, in the main, been at the leading edge of QIS worldwide. The early spearheading of this high-risk R&D effort by the EC has aided in the creation of a number of national investments in QIS with the research area now reaching a more mature stage of medium/high risk. Until now, European publication output and quality has been on a par (and even superior) with the US, while other nations have begun systematic ramp-up in QIS investments.

In the last years, significant growths in the research efforts within the field of QIS have been made worldwide. Especially the US has fostered their research activities, supported by a number of public funding agencies, namely the National Science Foundation (NSF) and the Defense Advanced Research Projects Agency (DARPA). Today, the US investment in QIPC of estimated 149 Million USD represents nearly 50 % of the worldwide research expenses in this field. Other important nations are Canada (31.6 MUSSD), Japan (20.0 MUSD), Australia (19.1 MUSD), Brazil (15.2 MUSD) and China (14.2 MUSD).

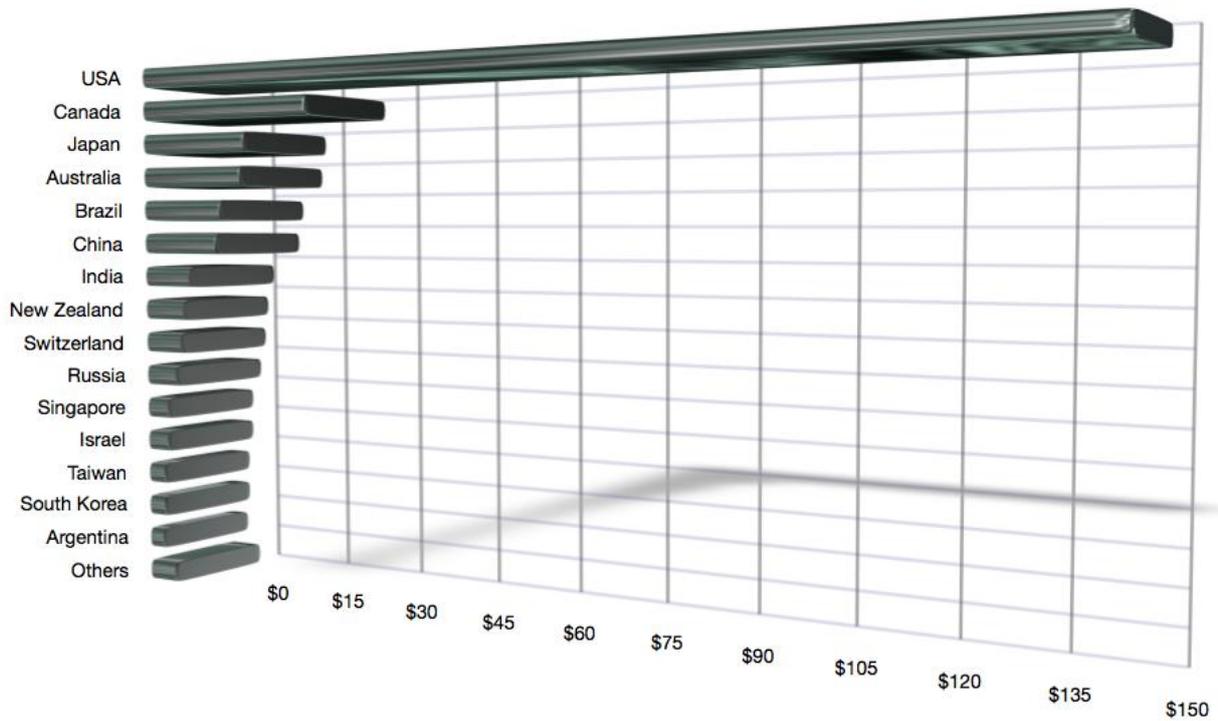

To retain our leading position in research and to capitalize on the Commission's already significant investments in QIS (50M€ in FP5 and FP6), it is vital to ensure that the EC investment in QIS remains competitive with the US and other national/continental QIS investors. Our current intelligence indicates that a Commission investment of 8M€/yr will compete very

poorly with the US, who now federally invests 149 MUSD/yr

Funding policies and European QIPC competitiveness

Indeed, Australia, with a population of 20 million (EU population is ~450 million), will be federally investing, \$8MAUS/yr (5M€/yr), in a coherent QIS effort through its National Centers of Excellence. Among the strongest threats to Europe's lead role in Q/NIST/IS is the US FoQuS programme. The FoQuS programme (by the US Defense Advanced Research and Projects Agency), was initially tabled in early 2004 with a specific targeting of quantum computer QIS in a single project funded to ~90MUSD over four years, with worldwide researcher

participation. This programme has not yet been fully launched but remains under consideration by the US for 2005. With the very significant international targeting of QIS ramping up around the world it is imperative that Europe remains competitive. QIS R&D support on the scale of ~8M€/year puts Europe at the lower end of worldwide QIS funding support. With such a potential decrease in international competitiveness, there is considerable risk that European research in QIS and the resulting technology developments (commercial and defense), will not be sustainable, leaving Europe reliant on importing such developed QIS technology from abroad.

Estimated funding of QIPC outside Europe in Million USD. Salaries represent 64% of the direct costs (costs without any overhead), whereas experimental equipment represents 36% of the direct costs. Overhead costs that are customary in the place have been added

3.4 THE EUROPEAN FLAVOR, VISIONS AND GOALS

The broader scope of the European effort

In comparison with the international QIPC programs, the characteristics of the European effort are its broader scope,

beyond the focus on specific issues like security or special applications like factoring, as for example in the US and in Australia. Moreover, there is a much stronger theoretical component and emphasis on fundamental physics. Clearly, Europe has achieved a critical mass in this much broader context of QIPC which includes both theoretical and experimental physics: atomic physics, quantum optics and laser physics, high energy and mathematical physics, condensed matter, etc., as well as from other disciplines like computer science, mathematics, material science, several areas in engineering, etc.

The European vision

The European vision is to advance quantum information processing in such a wider context which includes the spectrum from fundamental quantum physics to applications in science and engineering.

Novelty and Innovation

To remain competitive Europe should nurture QIS technology innovation from fundamental research

One of the most challenging aspects in creating a new technology is the transition of basic research with its accompanying spin-off technologies, into more application driven research where inherently QIS based applications are researched and developed. The earliest such QIS-driven application is quantum cryptography with a number of QCrypto SMEs already in operation worldwide. General purpose quantum computation, e.g. for factoring of large integers and related applications maybe a long-term goal. But quantum memories/repeaters and multiparty QIS software, will be developed in the next five years with the potential for even greater innovation and SME/Multinational commercialisation. Although there have been efforts by the US and others to make this transition to a more innovation based QIS research community, they have not succeeded so far and Europe, through FP6 QIPC-PI, has the opportunity to begin facilitating this transition and in this way could gain at least a two-year competitive advantage over others. The particular emphasis by the project QAP to build a complete QIS R&D pipeline from fundamental research in computer

science, quantum algorithms and quantum information theory through to experimental development, where the overall emphasis is to develop truly QIS based applications in the medium-term, is unique in the world. No other nation/continent has managed to create such a synergy. Some of the FET-PI QIPC Integrated Projects contain over 13% industrial partner effort and this connection to industry will be proactively targeted and ramped up over the coming five years through the cooperative efforts of FET-PI QIPC IPs. The inclusion of a variety of QIS projects, some focused on fundamental research and some focused on applications, in the FET-PI will put Europe in a strategic position worldwide.

Convergence

QIS research is expanding beyond its traditional boundaries as device complexity grows and many different physical QIS elements are integrated.

There is a convergence of many information technologies towards QIS. Examples include, integrated photonics research both linear & nonlinear, quantum effects in nanotechnology & materials science, interfacing classical information systems with quantum-atomic systems, quantum solid-state systems, and quantum photonic-systems. Such emerging plurality of QIS is already recognized by the NSF, where QIS R&D has a presence in many Divisions of the NSF, e.g. Physics, Computer-Communication Foundations, Nanoscale Science and Engineering, and Information Technology Research Divisions. Thus, the QIS portfolio encompasses some of the E-Nano R&D effort.

European Research Area

QIS has the potential to bring the vision of a true European Research Area into being.

QIS R&D is expanding throughout Europe with significant New-States contributions (Poland/Slovakia). The European QIS research community is well organized (thanks to previous networking initiatives by the EC), and many nations will work coherently in a recently funded ERA-NET project in Quantum Information Science and Technology (ERA Pilot-QIST). The creation of truly European Research Area is essential and justifies additional funds for the QIPC programme.

3.5 QIPC IN A WIDER SCIENTIFIC AND TECHNOLOGICAL CONTEXT

A new paradigm for computing and communicating

QIPC has arisen in response to a variety of converging scientific and technological challenges. The main one being the limits imposed on information processing by the

fundamental laws of physics. Research shows that quantum mechanics provides completely new paradigms for computation and communication. Today the aim of QIPC is to understand how the fundamental laws of quantum physics can be harnessed to improve the acquisition, transmission, and processing of information. The classical theory of information and computation, developed extensively during the

twentieth century, although undeniably very successful up to now, cannot describe information processing at the level of atoms and molecules. It has to be superseded by a quantum theory of information. What makes the new theory so intellectually compelling is that the results are so surprising and with so far reaching consequences.

During the last ten years, QIPC has already established the most secure methods of communication, and the basic building blocks for QIPC have been demonstrated in technologically challenging experiments. Efficient

QIPC is ready for real-life applications

quantum algorithms have been invented, and in part implemented, and one of the first non-trivial applications will be the development of quantum simulators with potential applications in, for example, material sciences. On the technological side these developments are closely related to improving atomic clocks and frequency standards.

QIPC is intrinsically multidisciplinary

Future advances in the field will require the combined effort of people with expertise in a broad range of research areas. At the same time, the new conceptual and technical tools developed within QIPC may prove fruitful in other fields, in a process of cross-fertilization encompassing a wide variety of disciplines (including, for instance, quantum statistics, quantum chaos, thermodynamics, neural networks, adaptive learning and feedback control, chemistry, quantum control, complex systems). This profoundly interdisciplinary character is one of the most exhilarating aspects of the field. Its potential is being recognized by commercial companies all over the world. A new profile of scientists and engineers is being trained to confront the challenges that lie beyond the end of the VLSI scaling. It is clear that advances in QIPC will become increasingly critical to the European competitiveness in information technology during the coming century.

Need for an early dialogue between policy, science and industry

Yet, at the moment most activities are focused on basic research in universities and there is very limited collaboration between QIPC scientists and industry. To maintain and develop competitiveness within this field in comparison to other research areas enhanced structuring and co-ordination of efforts on a European level are necessary. At the same time, a strong QIPC field ready for future industrial applications requires the involvement of relevant industry as well. In this sense an early dialogue needs to be established between science, policy, and industry in order to develop a common vision about the future of QIPC in Europe.

Potential QIPC spin-offs

QIPC is definitely centered in the realm of basic research with its own distinct goals and applications in computation, communication and information processing in all its aspects. Furthermore QIPC research will have a deep impact on several EU strategic priorities. There is significant potential impact on technology, economics and social issues. In addition there are several spin-offs with applications in other fields of science, engineering and technology.

QKD

- The rapid growth of information technology has made our lives both more comfortable and more efficient. However, the increasing amount of traffic carried across networks has left us vulnerable. Cryptosystems are usually used to protect important data against unauthorized access. Security with today's cryptography rests on computation complexity, which can be broken with enormous amounts of calculation. In contrast, quantum cryptography delivers secret crypto-keys whose privacy is guaranteed by the laws of Nature. Quantum key distribution (QKD) is already making its first steps outside laboratories both for fiber based networks and also for communication via satellites. However, significant more basic research is necessary to

increase both the secret bit rate and the distance. This is the field of Quantum Communication.

- The development of quantum information theory together with the development of quantum hardware will have a significant impact on computer science. Quantum algorithms, as for example Shor's algorithm for factorizing numbers with implications for security of classical crypto-protocols, indicate that quantum computers can perform tasks that classical computers are believed not to be able to do efficiently. A second example is provided by quantum simulations far beyond the reach of conventional computers with impact on various fields of physics, chemistry and material science. In addition, QIPC is redefining our understanding of how "physical systems compute", emphasizing new computational models and architectures.

New computational models and architectures

- QIPC is related to the development of nanotechnologies. Devices are getting smaller and quantum effects play an increasingly important role in their basic functioning, not only in the sense of placing fundamental limits, but also opening new avenues which have no counterpart in classical physics. At the same time development of quantum hardware builds also directly on nanotechnologies developed for our present day computing and communication devices, and provides new challenges for engineering and control of quantum mechanical systems far beyond what has been achieved today. An example is the integration of atom optical elements including miniaturized traps and guides on a single device, capable of working as a quantum gyroscope, with extremely large improvements in sensitivity both for measuring tiny deviations of the gravitational field, as well as for stabilizing air and space navigation. In spintronics, a new generation of semiconductor devices is being developed, operating on both charge and spin degrees of freedom together, with several advantages including non-volatility, increased data processing speed, decreased electric power consumption, and increased integration densities compared to conventional semiconductor devices.

Synergies with nanotechnologies

- Quantum mechanics offers to overcome the sensitivity limits in various kinds of measurements, for example in ultra-high-precision spectroscopy with atoms, or in procedures such as positioning systems, ranging and clock synchronization via the use of frequency-entangled pulses. Entanglement of atoms can help to overcome the quantum limit of state-of-the-art atom clocks which has been already reached by leading European teams. On the other hand, the quantum regime is being entered also in the manipulation of nanomechanical devices like rods and cantilevers of nanometer size, currently under investigation as sensors for the detection of extremely small forces and displacements. Another example is the field of quantum imaging,

Quantum metrology

where quantum entanglement is used to record, process and store information in the different points of an optical image. Furthermore, quantum techniques can be used to improve the sensitivity of measurements performed in images and to increase the optical resolution beyond the wavelength limit.

4. ASSESSMENT OF CURRENT RESULTS AND OUTLOOK ON FUTURE EFFORTS

4.1 QUANTUM COMMUNICATION

Quantum communication is the art of transferring a quantum state from one location to another. Quantum cryptography was discovered independently in US and Europe. The American approach, pioneered by Steven Wiesner, was based on coding in non-commuting observables, whereas the European approach was based on correlations due to quantum entanglement. From an application point of view the major interest is Quantum Key Distribution (QKD), as this offers for the first time a provably secure way to establish a confidential key between distant partners. This key is then first tested and, if the test succeeds, used in standard cryptographic applications. This has the potential to solve a long-standing and central security issue in our information based society.

While the realisation of quantum communication schemes is routine work in the laboratory, non-trivial problems emerge in long-distance applications and high bit rate systems. At present, the only suitable system for long-distance quantum communication is photons. Other systems such as atoms or ions are studied thoroughly; however their applicability for quantum communication schemes is not feasible within the near future, leaving photons as the only choice for long-distance quantum communication. One of the problems of photon-based schemes is the loss of photons in the quantum channel. This limits the bridgeable distance for single photons to the order of 100 km with present silica fibers and detectors. Recent quantum cryptography experiments already come close to such distances. In principle, this drawback can eventually be overcome by subdividing the larger distance to be bridged into smaller sections over which entanglement can be teleported. The subsequent application of so-called "entanglement swapping" and "quantum memory" may result in transporting of entanglement over long distances. Additionally, to diminish decoherence effects possibly induced by the quantum channel, quantum purification might be applied to eventually implement a full quantum repeater.

There are two media that can propagate photons: optical fibers and free space. Each of these two possible choices implies the use of the corresponding appropriate wavelength. For optical fibers, the classical telecom choices are 1300 and 1550 nm and any application in the real world of quantum communication in fibers has to stick to this choice. For free space the favored choice is either at shorter wavelengths, around 800 nm, where efficient detectors exist, or at much longer wavelengths, 4-10 microns, where the atmosphere is more transparent.

Recall that quantum physics can deliver «correlations with promises». In particular it can deliver at two locations strictly correlated strings of bits with the promise that no copy of these bits exist anywhere in the universe. This promise is guaranteed by the laws of Nature, they do not rely on any mathematical assumption. Consequently, such two strings of correlated bits provide perfect secure keys ready to be

used in standard crypto-systems. However, for quantum physics to hold its promise, truly quantum objects, like photons, have to be sent from one location to the other. Since quantum objects interacting with the environment lose their quantumness, i.e. become classical objects, it is crucial to isolate the photons during their propagation. Consequently, it is of strategic importance to develop the technology to send photons from one location to a distant one while preserving its truly quantum nature. The test of this quantumness consists in measuring the correlations and proving that they do violate a certain inequality, known as the Bell inequality.

From the present situation, where commercial systems already exist, there are three main directions to be pursued, which we review one after the other.

4.1.1 FIBER BASED SYSTEMS

Towards higher bit rates

1. Fast electronics, this includes fast sources and fast and low-loss phase modulators. This is mainly a (non-trivial) engineering problem.
2. Improved detectors: lower dark counts (<10-6 per ns), shorter dead times (<1 μ s), less time-jitter (<100 ps) and higher detection efficiency (>15%). This is a non-trivial solid state physics challenge.
3. Invent and investigate new protocols inspired by existing and reliable components, like "decoy states" [1] and the SARG protocol [2]. Also protocols based on fast homodyne detection methods can be thought of, such as the continuous variables protocols [3]. This is mainly a matter of the physicists' imagination!
4. It is known that existing classical communication procedures and security proofs do not make optimal use of the correlations that are generated in the physical set-up and can be improved. Further improvement in secure key rate can follow from a scenario of trusted sending and receiving devices which cannot be manipulated by an eavesdropper. It would also be valuable to have security proofs easier to understand for classical cryptographers.
5. Single-photon sources have made spectacular progress in the last years [4], but it is not clear yet whether they will be able to fulfill practical needs for high repetition rates, high coupling efficiency and electronic cooling (no liquid helium). It is not even necessary to use single photon sources since also QKD with weak laser pulses can be proven to be secure; see e.g. [5]. Moreover, the performance of ideal single photon sources can also be achieved using laser pulses with a phase reference, as has been proven by a recent analysis by Koashi [6]. Fourier-transform limited single-photon sources with negligible

time-jitter could also be used as building blocks for linear optics quantum computing.

6. Quantum communication with entangled states will be important to further develop quantum teleportation and entanglement swapping in view of their possible use in connection future quantum computers.

Europe has a leading role for point 6, while it is competing with the US for 3 and 4 (and also with Japan for 5). US and Japan are ahead concerning 1 and 2.

Towards longer distances

In today's system the distance is limited by the fiber loss and the detector dark-counts: at large distances the dark-counts dominate the signal. To improve the distance one can, from the simplest and less effective to the most challenging and most effective:

1. Improve the detectors: lower dark counts automatically increase the distance. However, the bit rate decreases exponentially with distance.
2. Improve the fibers: air-core photonic band-gap fibers have the potential to surpass silica fibers. (Even pure silica core photonic bandgap fibers could improve on today's telecom fibers, but only by at most 0.05 dB/km). This is a tremendous engineering challenge, with applications which would impact the whole field of optical telecommunications!
3. Use quantum relays exploiting quantum teleportation and entanglement swapping [7]. Dividing the connection in sections allows one to open the receiving detector less frequently, lowering thus the dark-count rate. For any given detector efficiency, this allows one to gain a factor of about 5 in distance. But the maximal distance is still limited and the bit rate still decreases exponentially with distance. Quantum relays require entangled photon sources. It should be stressed that quantum relays are anyway necessary for quantum repeaters. Today's longest distance demonstration is a quantum teleportation lab experiment connecting three 2 km long sections. The next crucial milestone in this direction will be a field demonstration over tens of km of entanglement swapping.
4. Use quantum repeaters: fully developed quantum repeaters have the potential of extending quantum communication to arbitrary long distances with a constant bit rate [8]. It is extremely challenging physics and still basic research. A quantum repeater requires a quantum memory. The latter has to outperform an optical fiber delay loop. This important milestone is described in section 4.1.3.

In this subfield, Europe is presently the leader; except for the first one, where the US and Japan are ahead.

Quantum continuous variables

Besides qubits, quantum continuous variables (QCV) have emerged as a new tool for developing novel quantum communication and information processing protocols. Encoding quantum continuous information into the quadrature of a light mode, or into the collective

spin variable of a mesoscopic atomic ensemble, has proven to be a very interesting alternative to the standard concept of quantum bits. Several experimental breakthroughs have been achieved recently demonstrating this concept, namely the quantum teleportation of a coherent state, the preparation of distant entangled atomic ensembles, or the implementation of a quantum key distribution scheme relying on coherent states, or the realization of a quantum memory based the light-atoms interface. Beyond these major experimental results, a large number of theoretical ideas have appeared in the literature, proposing to use QCV for achieving dense coding, entanglement purification or distillation, error correcting codes, cloning or telecloning, memories based on light-atoms interfaces, etc. In addition, some fundamental studies have been carried out on the entanglement of multimode Gaussian states, or on the capacity of Gaussian quantum channels.

These results are stimulating more research work, with many theoretical and experimental developments, especially in the directions of improved and/or novel quantum communication and secret sharing protocols, quantum memories and quantum repeaters using the light-atoms quantum interface, and the use of squeezed, or entangled, or even non-Gaussian states of light in order to make some new information processing with continuous variables possible.

Europe is at the forefront of the developments in this subfield, both experimental and theoretical. For example, European teams were the first to demonstrate the entanglement of two atomic ensembles and to realize a continuous-variable quantum key distribution scheme. Recently, quantum cloning and quantum memory were realized for continuous variables. Most of the theoretical work on continuous-variable entanglement is also due to European teams.

New applications and protocols

The field of quantum communication is still very young, having been essentially unknown until 10 years ago. One should expect new ideas and leave open space for basic research. From the theoretical point of view, there are several problems that have to be considered in the context of quantum communication. First of all, since the field is still very young, one should expect new applications related to both the efficiency as well as the secrecy in communications. Examples of the first can be connected to secret voting protocols, digital signatures, or fingerprinting. Examples of the second field could be, for example, connected to dense coding, or agenda protocols. Apart from that, there are still several theoretical open questions of crucial importance for quantum cryptography. They are related to the tolerance to noise of current protocols (both with one and two way communication), the connection between single photon and continuous variable protocols, and the search for more efficient and fast ways of distributing keys.

Quantum communication protocols can be often understood as entanglement manipulation protocols. An important class of these protocols delivers classical data with properties derived from the underlying quantum state. For this class the question arises whether one can replace the quantum manipulation and subsequent measurement by another two-step

procedure that first measures the quantum states and then performs classical communication protocols on the resulting data to complete the task. Such an implementation would be preferential in real implementation, as is illustrated in the case of quantum key distribution. It is important to study under which circumstances such a replacement can be done.

For many quantum communication applications it is important to operate in a larger dimension Hilbert space. This can be obtained by preparing two photons entangled in more than one degree of freedom (hyperentangled) and increasing in this way the number of qubits. Other proposals concern the generation of d-level quantum systems (qudits) by using different degrees of freedom.

4.1.2 FREE SPACE SYSTEMS

Despite the achievements of quantum communication experiments, the distances over which entanglement can be distributed in a single section, i.e. without a quantum repeater in-between, are by far not of a global scale. Experiments based on present fiber technology have demonstrated that entangled photon pairs can be

separated by distances ranging from several hundreds of meters up to 10 km in the field (and 50 km in the lab), but no improvements by orders of magnitude are to be expected. On the other hand, optical free-space links could provide a unique solution to this problem since they allow in principle for much larger propagation distances of photons due to the low absorption of the atmosphere in certain wavelength ranges. Also, the almost non-birefringent character of the atmosphere guarantees the preservation of polarization entanglement to a high degree. Free-space optical links have been studied and successfully implemented already for several years for their application in quantum cryptography based on faint classical laser pulses. Recently a next crucial step was demonstrated, namely the distribution of quantum entanglement via a free-space link, which was verified by violating a Bell inequality between two distant receivers without a direct line of sight between them.

Towards Space Quantum Communication

Terrestrial free-space links suffer from obstruction of objects in the line of sight, from possible severe attenuation due to weather conditions and aerosols and, eventually, from the Earth's curvature. They are thus limited to distances typically of the same order as the fiber links. To fully exploit the advantages of free-space links, it will be necessary to use space and satellite technology. By transmitting and/or receiving either photons or entangled photon pairs to and/or from a satellite, entanglement can be distributed over truly large distances and thus would allow quantum communication applications on a global scale.

A significant advantage of satellite links is that the attenuation of a link directly upwards to a satellite is comparable to about 5–8 km horizontal distance on ground. Proof-of-principle experiments for such distances in free space exist for weak laser pulses.

Several studies are currently underway and suggest the feasibility of space-based experiments based on current technologies [1-4].

Many of the goals to be achieved in free-space quantum communication are shared with fiber-based technology, e.g. the improvement of detectors or the development of quantum repeater technology. Additional challenges and goals are

1. Free-space distribution of entanglement over distances above 5 km.
2. Implementation of active and/or adaptive optics techniques for single photons.
3. Free-space teleportation of a single-photon state.
4. Free-space entanglement swapping.
5. Free-space quantum cryptography (with discrete or continuous variables) demonstration of single-photon uplinks to a satellite.
6. Demonstration of a single-photon down-link from a satellite.
7. Quantum cryptography between two widely separated locations on Earth via satellites.
8. Development of narrow-band sources of entangled photons for daylight operation.
9. Implementation of an entangled-photon source on a satellite.

10. Teleportation of a photon state up to a satellite.
11. Teleportation of a photon state between two ground locations via a satellite.
12. Teleportation of a photon state down from a satellite.
13. Satellite-satellite quantum communication.

Evidently this line of research necessitates both significant basic investigation as well as very specific and advanced technological development. At present various considerations and studies of feasibility are being undertaken. These focus on issues like the possible use of the existing telescopes for optical communication with satellites, e.g. OGS on Tenerife, or the requirements for satellite-based sources of photonic quantum states. Given sufficient funding it should be possible to have a first source of entangled photons on a satellite within about 10 years from now.

4.1.3 QUANTUM INTERFACES AND MEMORIES

An interface between quantum information carriers (quantum states of light) and quantum information storage and processors (atoms, ions, solid state) is an integral part of a full-scale quantum information system. In classical communication information is transferred encoded in pulses of light. The pulses are detected by photodetectors, transformed into electrical current pulses, amplified by electronics, and sent to computers, phones, etc. This transformation of light into electrical signals forms classical light-matter interface. In quantum information processing simple classical detection of light is inadequate for recording into memory, because it destroys the quantum state by adding extra noise to it. Hence a quantum interface has to be developed. Instead of direct transformation of light pulses into electrical pulses, as in classical communication, quantum state transfer of light qubits (or continuous variables) with atomic qubits (or continuous variables) has to be developed in QIPC. Certain kinds of quantum interfaces, based on cavity QED, are discussed in part 6.2 with an emphasis on computing tasks. Other kinds of quantum interfaces,

such as quantum memory and long-distance quantum teleportation of long lived atomic states, are important for communication and quantum secret sharing tasks. It is obvious that long lived entanglement shared over a long distance requires transfer of entanglement from light (the long distance carrier) to atoms (the long lived objects). Such transfer can only be done via a special light-atoms quantum interface. Distant long lived entangled objects can serve as secure "quantum identification cards". These kinds of tasks can be addressed via such physical implementations as atomic ensembles, which are easier to implement and to scale.

Currently various aspects of light-atoms quantum interface and memory are investigated mainly by the European groups at Copenhagen University (E. Polzik); University of Aarhus, Denmark (K. Molmer and M. Drewsen); Max Planck Institute for Quantum Optics, Garching, Germany (I. Cirac and G. Rempe); Institute for Photonic Sciences, Barcelona, Spain (M. Mitchell); University of Kaiserslautern, Germany (M. Fleischhauer); University of Heidelberg, Germany (J. Schmiedmayer); and Lab Kastler Brossel, CNRS, Paris (M. Pinard and E. Giacobino). In the US this research is primarily carried out at Harvard University (M. Lukin); Caltech (J. Kimble), University of Michigan, Ann Arbor (Ch. Monroe); and Georgia Institute of Technology, Atlanta (A. Kuzmich).

Quantum memory for light and quantum repeaters

For coherent pulses used in classical communications, a classical approach via simple detection limits the fidelity of the memory to 50%. For non-classical states the fidelity of the classical memory is even lower. Classical communications where weak pulses of light of different colors are sent in parallel (frequency multiplexing) approach quantum limits exponentially with time (at today's pace it will be reached by 2020). Hence new - quantum - approaches to memory have to be considered for both quantum and classical communications.

State of the art: Proposals for quantum memory for light have been put forward during the past decade, in Europe and in the US. Recently the first quantum memory for a weak coherent pulse has been demonstrated in Europe [1]. A quantum memory which is to be used for storage, and not for quantum processing, is based on a simple physical system consisting of a small cell filled with atomic gas at room temperature – an atomic ensemble. Demonstrated quantum state storage time of up to 4 msec corresponds to propagation time over a distance of about 1000 km. The storage cell works close to the free space propagation wavelength.

Visions and perspectives: Quantum memory provides a stored version of quantum cryptography and quantum secret sharing (in the long run, counterfeit proof bank cards, etc). It also poses a potential threat to quantum cryptography via more efficient eavesdropping protocols, and hence has to be taken seriously in quantum communication security issues. Quantum memory for light provides a necessary ingredient for quantum networks, as discussed in the next section. Future work on quantum memory based on the atomic ensemble approach should be concentrated on

1. Extending memory capabilities to single photon/qubit storage.
2. Achieving efficient retrieval of the stored quantum state.
3. Improving the fidelity of storage.
4. Quantum error correction necessary for achieving extra long storage times.
5. Memory micro-cell arrays for multi-channel storage including quantum image storage – quantum holograms.
6. Exploring other types of atomic/solid state ensembles useful for storage applications; solid-state system such as those used for slow light experiments are potentially suitable for quantum memory and should be investigated.
7. Developing probabilistic repeater schemes possibly integrated using atoms on chip technology.

European labs are presently ready to tackle each of the above strategic challenges.

Long distance atomic teleportation and repeaters

State of the art: Atomic teleportation over a distance of a fraction of a millimeter has been recently demonstrated by two groups, in Europe and in the US. Long distance teleportation of atomic states requires interface with light. A significant progress has been achieved on the way towards implementation of a repeater primarily by US groups [Lukin, Monroe, Kimble, Kuzmich and Wuletich] where a strong experimental effort on Electromagnetically Induced Transparency (EIT) stored light and quantum memories involving ensembles as well as single atoms [2] can be identified. Entanglement of atomic ensembles at a distance of half a meter has been demonstrated in Europe [3]. The technology is simple and relies on glass cells filled with atomic gas at room temperature. At present the technology is limited to near infrared wavelength suitable for free space propagation.

Vision and perspectives: Long distance deterministic teleportation will allow realization of distributed quantum networks. Extension of entanglement of atomic ensembles to up to a kilometer is possible with specially

designed optical setups. For yet longer distances quantum repeaters proposed in Europe present an option. Towards this goal a combination of a repeater with entangled trapped ions will be useful. Another possible way to realize an efficient repeater is to use atomic ensemble quantum memory [1] to store one photon of an entangled pair produced by downconversion. The repeater approach may allow teleportation of atomic states over many kilometers.

1. Challenges and directions of future work are similar to those listed for quantum memory, i.e.:
2. Extending memory capabilities to single photon/qubit storage.
3. Achieving efficient retrieval of the stored quantum state.
4. Improving the fidelity of storage.
5. Exploring other types of atomic/solid state ensembles useful for storage applications; solid-state system, atoms on a chip.

Key research groups in Europe have been shown in the beginning of the section.

4.2 QUANTUM COMPUTING

Information processing nowadays is commonly implemented using quantities such as charges, voltages, or currents in electronic devices which operate on the basis of classical physics. Instead, Quantum Computing (QC) and more generally, quantum information processing (QIP) employ the laws of quantum mechanics for information processing. For such devices, corresponding building blocks are quantum bits (qubits) and quantum registers, and the basic gate operations are given by logical and coherent operations on individual qubits (single qubit operations) and controlled coherent interactions between two qubits (two-qubit operations) such that the state of the target qubit is changed conditional to the state of the controlling qubit.

In principle, a large scale quantum computer can be built using these primitives which must be realized by a controllable quantum system, provided the physical

system meets the following requirements (DiVincenzo criteria):

1. System is comprised of well characterized qubits and allows for scalability.
2. Ability to initialize the state of the qubits.
3. System provides long coherence times, much longer than a gate operation time.
4. A universal set of gates is experimentally feasible.
5. Qubit specific measurement capability.
6. Ability to interconvert stationary and flying qubits.
7. Faithful transmission of flying qubits between specified locations.

At present, there are a number of technologies under investigation for their suitability to implement a quantum computer. No single technology meets currently all of

these requirements in a completely satisfactory way. Therefore, the ongoing research on quantum information processing is highly interdisciplinary, diverse and requires a coordinated effort to create synergies while the common goal is the implementation of a working quantum processor. While at present several approaches have demonstrated basic gate operations and are even able to prove that quantum computing has become reality with few qubits, large scale quantum computation is still a vision which requires ongoing research for many years to come.

The long-term goal in quantum computation is, of course, a large-scale quantum computer which will be able to efficiently solve some of the most difficult problems in computational science, such as integer factorization, quantum simulation and modeling, intractable on any present or conceivable future classical computer.

Therefore, the general problems to be solved for QC and QIP are in particular

- Identification of the best suitable physical system which allows for scalability, coherence and fast implementation of QIP.
- Engineering and control of quantum mechanical systems far beyond anything achieved so far, in particular concerning reliability, fault tolerance and using error correction.
- Development of a computer architecture taking into account quantum mechanical features.
- Development of interfacing and networking techniques for quantum computers.
- Investigation and development of quantum algorithms and protocols.
- Transfer of academic knowledge about the control and measurement of quantum systems to industry and thus, acquisition of industrial support and interest for developing and providing quantum systems.

4.2.1 TRAPPED IONS

A. Physical approach and perspective

Ion trap quantum computation is based on schemes devised by Cirac and Zoller [1]. A quantum register is provided by strings of ions, each representing a physical qubit. The system satisfies in principle all DiVincenzo criteria and most of the criteria have been experimentally demonstrated. While the originally proposed system is scalable in principle, practical scalability requires additional techniques such as interconnecting via photons (flying qubits) or moving one or more ions to operate as a messenger for quantum information. A more comprehensive summary of ion trap QIP is contained in the US QIST roadmap [2]. Another related approach is to use electrons confined in a scalable system composed by an array of Penning traps. This scheme was devised by Ciaramicoli et al [3.] Although not yet experimentally implemented, it conceivably satisfies all the DiVincenzo criteria as well.

Currently, experimental ion trap QIP is pursued by 10 groups worldwide, 6 of which are located in Europe [R. Blatt (Innsbruck, AT), M. Drewsen (Aarhus, DK), P. Gill (Teddington, UK), W. Lange (Sussex, UK), A. Steane (Oxford, UK), Ch. Wunderlich (Maynooth, EI)], 3 more

groups are currently setting up ion trap experiments for QIP in Europe [J. Eschner (Barcelona, ES), T. Schaetz (MPQ Garching, DE), F. Schmidt-Kaler (Ulm, DE)]. Experiments with trapped electrons are currently being set up only in Europe by the groups of G. Werth (Mainz, DE) and F. Schmidt-Kaler (Ulm, DE).

On the theory side there is J.I. Cirac (MPQ Garching, DE), K. Molmer (Aarhus, DK) and P. Zoller (Innsbruck, AT); for trapped electrons P. Tombesi (Camerino, IT).

B. State of the art

With trapped ions, qubits are implemented using either two levels out of the Zeeman- or hyperfine manifold or employing a forbidden optical transition of alkaline earth, or alkaline earth-like ions. The DiVincenzo criteria are currently met as follows:

1. Strings of up to eight trapped ions are routinely loaded to a linear trap.
2. Ion strings can be cooled to the ground state of the trapping potential, and thus are prepared for implementing the Cirac-Zoller scheme. Using various techniques of individual ion manipulation, the register can be initialized to arbitrary internal and external states.
3. Qubit decay times for individual hyperfine qubits of more than 10 minutes have been observed, however, this requires magnetic-field "insensitive" transitions. For optical transitions, decoherence is limited by spontaneous decay which, however, is orders of magnitudes slower than a single gate operation. Long-lived quantum memory ($T > 1s$) using magnetic field independent qubit levels and decoherence-free subspaces have been demonstrated.
4. Individual ion manipulation (pulsed Rabi oscillations), as well as two-qubit gate operations (Cirac-Zoller gate, geometric phase gate, entangling gate) have been demonstrated. Multi-particle entangled states using 4-6-ion GHZ-states and 4-8-ion W-state have been also achieved.
5. State-sensitive light scattering (observation of quantum jumps) is routinely used with trapped ions and detection efficiencies of more than 99.9% are readily obtained.
6. For converting stationary (ion) qubits into flying (photon) qubits, the techniques of cavity quantum electrodynamics (CQED) are used and several experiments are currently under way, no results are available at this time.
7. Faithful transmission of photonic qubits between two quantum computer nodes was theoretically shown to be feasible; a transfer protocol is available, however, at this time no experimental work is carried out yet. Instead, over short distances, and for the transfer of quantum information within a quantum processor, ions can be moved and/or teleportation protocols may be used.

C. Strengths and weaknesses

At present, ion trap QIP provides most of the requirements for first-generation quantum computation experiments. In particular, the long coherence times of the ionic two-level systems provide a robust quantum

memory. Moreover, the near-unity state detection and the availability and operability of a universal set of gate operations make it already a test-bed for small-scale quantum computation. Furthermore, techniques to build large-scale ion trap quantum computers were outlined and their function was shown in first steps.

On the downside, motional decoherence by stochastically fluctuating fields (originating from trap electrodes) is not completely understood and must be reduced. Spontaneous emission must be avoided by all means; therefore decoherence-free subspaces need to be explored. Current technical constraints, such as the availability of laser sources, their respective stability and purity as well as fast optical detection and switching, need to be improved.

However, aside from the technical difficulties of scaling ion trap QIP up to larger devices, there is no fundamental problem in sight.

D. Short-term goals (next 3-5 years) (cf. also [2])

- Improve coherence of qubits by using magnetic field “insensitive” transitions, or decoherence free subspaces (for optical qubits).
- Reduce trap size and thus increase speed of operations.
- Identify and reduce sources of motional decoherence (needed for smaller traps).
- Implement error correction with 3 and 5 qubits, correct for phase and spin flip errors.
- Develop an “ion chip” as the basic building block for scaling ion trap QIP.
- Improve laser intensity and phase stability to reach fault-tolerant limits.
- Realize a “logical” qubit including error correction, i.e. encode a stable logical qubit in 5 physical qubits (“keeping a logical qubit alive”).
- Interface stationary and flying qubits.
- Demonstrate more quantum algorithms.
- Logical qubit operations (single L-qubits operations, gates between L-qubits).
- Identify an optimal ion.
- Implement quantum gates by frequency addressing or trapped electrons.

E. Long-term goals (2010 and beyond) (cf. also [2])

- Develop ion chips with integrated optics and electronics.
- Operations with several L-qubits.
- Fault-tolerant operations with multiple qubits.
- Show the feasibility of fault-tolerant quantum processors with trapped electrons.

4.2.2 NEUTRAL ATOMS, MOLECULES AND CAVITY QED

A. Physical approach and perspective

Neutral atoms and molecules provide a promising test bed for the development of scalable general purpose quantum processors, and for quantum simulators as special purpose quantum computers involving a very large number of qubits.

As in the case of ions, qubits can be represented by long-lived internal atomic and molecular states in electronic ground states (hyperfine levels, rotational states), or in metastable excited electronic states, which can be manipulated by optical and microwave fields. The unique promises of neutral atom quantum computing rest in particular on the well developed cooling and trapping techniques, as exemplified by laser cooling, realization of Bose Einstein condensates and quantum degenerate Fermi gases, in combination with optical, magnetic and electric traps, realized in free space or in cavities or on atom chips. Such techniques provide an ideal starting point to build and prepare large scale quantum registers with high fidelity. At present these trapping and cooling techniques are being extended to molecules, including, for example, electric on-chip traps for polar molecules. The scenarios of quantum computing with neutral atoms are directly linked to the development of specific trapping techniques. First, traps can be developed allowing the independent manipulation of the centre-of-mass degrees of freedom of individual atoms and molecules, including the addressing of single qubits, which is a necessary requirement for general purpose quantum computing; and massively parallel, identical manipulations of large number of qubits, as realized, for example, in the context of optical lattices with only global addressing, as is relevant in the context of quantum simulators of translational invariant condensed matter systems.

Entanglement of neutral atom or molecule qubits is based on the following physical mechanisms

- controlled qubit-dependent two-particle interactions, as for example in cold coherent collisions, or the dipole-dipole interactions between (highly) excited atomic states;
- cavity QED setups, where distant qubits are entangled via photon exchange, which plays the role of a quantum data bus.

In the cavity QED scenario, the atomic or molecular qubit is strongly coupled to a high-Q cavity, either in the optical domain by coupling to an electronic excitation, or in the microwave regime for a transition between Rydberg states or rotational states of a polar molecule. Two-qubit gates between distant qubits can be achieved via photon exchange as quantum data bus, in close formal analogy to the phonon data bus of collective oscillation modes in trapped ions. These cavity QED setups also provide a natural interface to quantum communication with photons.

Atoms and molecules can be stored in optical lattices, corresponding to an array of microtraps generated by counterpropagating laser fields. The dynamics of cold atoms loaded into optical lattices can be described by a Hubbard model, with atoms hopping between lattice sites, and interacting via collisions. Thus cold atoms in optical lattices provide a direct way to simulating condensed matter systems with a large number of bosons or fermions. In addition, loading an optical lattice from an atomic Bose-Einstein condensate provides via the superfluid-Mott insulator transition the preparation of a Mott phase with exactly one atom per lattice site, and thus the preparation of a very large number of atomic qubits. These can be entangled in parallel operations with qubit-dependent controllable 2-particle interactions, provided, for example, by coherent collisional interactions in combination with movable qubit (spin) dependent optical lattices. This provides the basis for a digital quantum simulator, for example of a spin lattice system, where the time evolution generated by the Hamiltonian is decomposed into a series of single and two-qubit gates performed in parallel on all qubits (spins).

For single atoms strongly coupled to an optical cavity, single photons for the purpose of exchanging quantum information between remote locations can be generated on demand and with high quantum efficiency. Protocols for generating a stream of photons with entanglement mediated and controlled by a single intracavity atom have been proposed. In addition to these deterministic mechanisms for entanglement, probabilistic protocols can be developed which are based on free space atoms emitting photons where entanglement is achieved by appropriate photon detection.

Currently, quantum computing with neutral atoms is investigated experimentally in several dozen laboratories worldwide, with half of them located in Europe. The European groups working with a controllable number of atoms include I. Bloch (Mainz, DE), T. Esslinger (Zurich, CH), P. Grangier (Orsay, FR), S. Haroche (Paris, FR), D. Meschede (Bonn, DE), G. Rempe (Garching, DE), and H. Weinfurter (Munich, DE). Several other groups are presently setting up new experiments, including W. Ertmer (Hannover, DE), E. Hinds (London, UK), J. Reichel (Paris, FR), and J. Schmiedmayer (Vienna, AT). The experimental program is strongly supported by implementation-oriented theory groups like H. Briegel (Innsbruck, AT), K. Burnett (Oxford, UK), J. I. Cirac (Garching, DE), A. Ekert (Cambridge, UK), P. L. Knight (London, UK), M. Lewenstein (Barcelona, ES), K. Mølmer (Aarhus, DK), M. B. Plenio (London, UK), W. Schleich (Ulm, DE), P. Tombesi (Camerino, IT), R. Werner (Braunschweig, DE), M. Wilkens (Potsdam, DE), and P. Zoller (Innsbruck, AT). In fact, European theory groups have played a crucial role in the development of QIPC science from the very beginning. The close collaboration between experiment and theory in Europe is unique, partly because of the support provided by the European Union.

B. State of the art

I. Quantum memories: The strength of using neutral atoms for QIPC is their relative insensitivity against environmental perturbations. Their weakness comes from the fact that only shallow trapping potentials are

available. This disadvantage is compensated by cooling the atoms to very low temperatures. So far, several different experimental techniques for trapping and manipulating neutral atoms have been developed:

Optical tweezers and arrays of optical traps allow for the preparation of a well-defined quantum state of atomic motion, as can be achieved by either cooling single atoms into the ground state of the trapping potential, or by loading a Bose-Einstein condensate into an optical lattice. While the first approach allows for individual atom manipulation, both methods offer the possibility of a massive parallelism, with many pairs of atoms colliding at once. The landmark results attained are:

- Single atoms were trapped with a large aperture lens, thus providing a three-dimensional sub-wavelength confinement.
- Single atoms were also loaded into the antinodes of a one-dimensional standing wave, and excited into a quantum superposition of internal states.
- This superposition was preserved under transportation of the atoms; coherent write and read operations on individual qubits were performed.
- A small number of atoms were loaded into a two-dimensional array of dipole traps made with a microlens array, and the atoms were moved by moving the trap array.
- Single atoms were loaded into the antinodes of a three-dimensional optical lattice, by starting from a Bose-Einstein condensate and using a Mott transition.

Atom chips: The ability to magnetically trap and cool atoms close to a surface of a micro-fabricated substrate (for example using micro-magnetic potential wells produced by micron-sized current carrying wires or microscopic permanent magnets) has led to an explosive development of atom chips in the past few years. Such devices are very promising building blocks for quantum logic gates due to their small size, intrinsic robustness, strong confinement, and potential scalability. The main accomplishments they have attained include:

- Cooling of atoms to quantum degeneracy (Bose-Einstein condensation).
- Transport of an ensemble of atoms using a magnetic conveyor belt.
- Very long coherence times by using appropriate qubit states.
- Multilayer atom chips with sub- μm resolution and smooth magnetic potentials.
- On-chip single-qubit rotation via two-photon transitions on hyperfine qubits.
- Single-atom detection using a fibre Fabry-Perot cavity.

Traps for polar molecules at the individual level have recently been proposed, based on microwave or electric fields, and are the subject of growing experimental investigation. On the experimental side,

- cold polar molecules at millikelvin temperatures have been produced by several different techniques, including deceleration of

supersonic molecules, filtering of slow molecules from a thermal ensemble, and Helium buffer gas cooling in a cryogenic environment,

- ensembles of cold polar molecules have been stored in magnetic or electric bottles.

II. Entangling gates: a variety of schemes have been proposed theoretically, based on interatomic interactions either direct (for instance collisional – possibly enhanced by Feshbach resonances – or between dipoles of Rydberg excited atoms) or mediated by a quantum data bus, i.e. a different degree of freedom (for instance photons in a high-finesse cavity mode).

Optical tweezers and arrays of optical traps are ideal to perform collisional gates, which require the preparation of a well-defined quantum state of atomic motion. In this field, a highly parallelized quantum gate was implemented by state-selectively moving the atoms, and making them interact using cold collisions. This landmark experiment has pioneered a new route towards large-scale massive entanglement and quantum simulators with neutral atoms.

Cavity QED, possibly in combination with optical dipole traps, is the most promising technique for realizing an interface between different carriers of quantum information, implemented either with free-space atoms emitting photons in a random direction (probabilistic approach), or with atoms in high-finesse cavities where the strong atom-photon coupling guarantees full control over photon emission and absorption (deterministic approach). The latter approach can be realized both with Rydberg atoms in microwave cavities as well as with ground-state atoms in optical cavities. If each atom resides in its own cavity, the scheme guarantees addressability and scalability in a unique way. As quantum information is exchanged via flying photons, the individual qubits of the quantum register can easily be separated by a large distance. The photon-based scheme is therefore ideal to build a distributed quantum network. The main achievements in this sector include:

1. Probabilistic approach in free space:
 - A single trapped atom has been entangled with a single photon.
2. Deterministic approach using microwave cavities: Circular Rydberg atoms and superconducting cavities are proven tools for fundamental tests of quantum mechanics and quantum logic:
 - Complex entanglement manipulations on individually addressed qubits with long coherence times have been realized.
 - Gates have been demonstrated.
 - New tools for monitoring decoherence of mesoscopic quantum superpositions have been developed.
3. Deterministic approach with optical cavities:
 - The strong atom-photon coupling has been employed to realize a deterministic source of flying single photons, a first step

towards a true quantum-classical interface.

- With single photons, two-photon interference effects of the Hong-Ou-Mandel type have been observed. These experiments demonstrate that photons emitted from an atom-cavity system show coherence properties well suited for quantum networking.
- Moreover, single atoms were optically trapped inside a cavity for such a long time that experiments can be performed with just one single atom.
- A novel cooling technique avoiding spontaneous emission was successfully implemented.
- Single or a small number of individually addressable atoms was deterministically transported in and out of a cavity by means of an optical conveyor belt.

All of the achievements reported in this section have been realized within European labs, and in many cases they are purely European achievements, in the sense that they are not to be found in labs outside Europe.

C. Present challenges

Most neutral-atom systems have not yet demonstrated two-qubit operations, mainly because the technology to perform single-atom experiments is relatively new (less than 10 years).

Optical tweezers and arrays of optical traps are most advanced in manipulating neutral-atom qubits.

1. In optical tweezers and small-scale dipole trap arrays, the main challenges are first to implement a two-qubit quantum gate, e.g., using a controlled collision of two atoms, and then to increase the size of the quantum register to more than 2 atoms.
2. In optical lattices, full addressability of each individual qubit of the closely spaced register is one of the main challenges.
3. In both scenarios, the speed of a gate must eventually be increased by implementing a collision which exhibits a large cross section, for example by involving Rydberg atoms or molecular (e.g., Feshbach) interactions.

Atom chips: Despite their recent achievements, experiments with atom chips are still facing a large number of challenges for implementing QIPC.

1. A quantum memory, that is the reading and writing of quantum information into single atoms or atomic ensembles must be realized.
2. Next, a two-qubit quantum gate, for example by employing a controlled collision, must be implemented.
3. The full demonstration of the potential provided by atom chips requires the realization of large-scale integration, e.g., with several 10 qubits.
4. Potential roughness very close (μm) to micro-fabricated structures is of concern for qubit storage and transport. Even though for current-carrying structures the problem can be solved

and compensated for by the design and fabrication methods as developed recently, micro-structures with fewer defects might be needed for permanent magnets.

5. Merging atom-chip technology and cavity QED is promising. High-finesse miniature optical or microwave cavities can be coupled to ground state or Rydberg atoms trapped on a chip. Coherence preserving trap architectures are an important first step towards a fully scalable architecture combining the best of both worlds.

Polar molecules: Research with polar molecules has just started and, hence, is still facing a large number of experimental challenges. Some of these are:

1. As laser cooling methods developed for atoms fail for molecules, new cooling techniques need to be developed to reach the ultracold regime.
2. The number of molecules and their density needs to be increased before collisions can be observed in electric trapping experiments.
3. Efficient molecule detection techniques must be developed in particular for experiments involving only single or a few molecules.

Cavity QED: The main difficulty in implementing QIPC protocols in present demonstration experiments is the enormous technological complexity required to obtain full control over both atoms and photons at the single-particle level.

1. The probabilistic approach suffers from the low efficiency of photon generation and detection, and the large solid angle of photon emission for a free-space atom.
2. The deterministic approach employing microwave cavities has intracavity-photon generation and absorption efficiencies close to 100%, and the implementation of simple algorithms is in view.
 - One of the main challenges is the demonstration of scalability. The preparation of a non-local entangled and possibly mesoscopic quantum state shared between two remote cavities is a major task.
 - Another challenge is the realization of quantum feedback or error correction schemes to preserve the quantum coherence of the field stored in a cavity with a finite quality factor.
3. The deterministic approach utilizing optical cavities has led to photon-emission efficiencies of up to about 30%. Challenges are
 - To entangle in a deterministic manner a single atom with a single photon, and to teleport the quantum states between distant photon-emitting and photon-receiving atoms.
 - In order to integrate individual quantum-network nodes into a scalable quantum-computing network, a set of individually addressable atoms located in different cavities must be implemented.
 - Moreover, single-photon quantum repeaters which are necessary to communicate quantum information over large distances need to be developed.

- Ultimately, the gate speed should be increased by installing a few-wavelength long cavity. The combination of such a micro-cavity with presently available trapping and cooling techniques is a challenge.

In the microwave domain, a method of deterministically transporting single atoms in and out of a cavity, for example by means of an optical conveyor belt, is needed to address the individual atoms of a stationary quantum register.

A major challenge for theory is to characterize and optimize the suitability of each of the available and proposed experimental systems as platforms for general-purpose quantum computing or rather for quantum simulation.

All of the strategic challenges in this section represent current or planned activity at European labs.

4.2.3 SUPERCONDUCTING CIRCUITS

A. Physical approach and perspective

Quantum computation with superconducting circuits exploits the intrinsic coherence of the superconducting state, into which all electrons are condensed. Quantum information is stored in the number of superconducting electrons (charge qubit), in the direction of a current (flux qubit) or in oscillatory states (phase qubit). Systems are fabricated with thin film technology and operated at temperatures below 100 mK. Measurements are performed with integrated on-chip instruments. Coupling between qubits can be made strong. In principle the system is scalable to large numbers. The US QIST roadmap gives more detailed information and references, though not quite up to date [1]. A general background is provided in [2].

Approximately 30 groups work on superconducting quantum bits in Europe, Japan, China and the USA. European groups in experiments are: D. Esteve and D. Vion (Saclay, FR), J. Rooij and H. Hamans (Delft, NL), P. Delsing (Chalmers, SE), A. Zorin (PTB, DE), E. Illichev (Jena, DE), A. Ustinov (Erlangen, DE), F. Hekking, O. Buisson (Grenoble, FR), J. Pekola (Helsinki, FI), S. Paroanu Jyväskylä, FI), D. Haviland (Stockholm, SE), C. Cosmelli and M. G. Castellano (Rome, IT), and others. In theory: G. Schön, (Karlsruhe, DE), R. Fazio (Pisa, IT) A. Wilhelm (München, DE), G. Wendin (Chalmers, SE), M. Grifoni (Regensburg, DE), G. Falci (Catania, IT), K. Bruder (Basel, CH), and others.

B. State of the art

1. Qubits can be readily fabricated with suitable parameters. Small variation of qubit parameters can be achieved.

2. Initialization proceeds by relaxation into the ground state before quantum operations start.
3. Single qubit operations are performed with microwave pulses or DC pulses.
4. 1-pulse Rabi oscillations and 2-3 pulse Ramsey or spin-echo signals have been realized.
5. Decoherence times of several microseconds have been observed, shortest time needed for a basic quantum operation is several nanoseconds.
6. a) With charge 2-qubit systems a controlled-not gate has been realized with DC pulses.
b) The presence of coupling has been demonstrated in flux qubits with spectroscopy.
7. Strong coupling, allowing exchange of a single photon, has been achieved between a harmonic oscillator and a qubit in two different types of qubit.
8. Rabi oscillation between two Josephson junction qubits has been achieved, and simultaneous single-shot readout has been performed to detect the anticorrelations in a Bell state.

All of these results have been achieved within Europe, apart from 6.a) (Japan) and 8 (USA).

C. Strengths and weaknesses

Strengths:

- High potential for scalable integrated technology.
- Strong coupling between qubits possible.
- Flexible opportunities with different qubit types.
- Mature background technology, 20 years of experience.
- Driver of applications in solid-state quantum engineering.
- Long history of pushing the limits of measurement towards quantum limits.
- Low-temperature or superconducting technologies necessary for integration with solid state microtraps for hybrid systems.

Weaknesses:

- Coherence limited by defects in tunnel barriers.
- Slight variation in qubit parameters associated with fabrication.

D. Short-term goals (next 3-5 years)

- Realize reliable two-qubit gates in all types of qubits.
- Realize non-destructive single shot readout of individual qubits in multi-qubit circuits
- Improve fidelity of operation and readout.
- Investigate and eliminate main sources of decoherence.
- Develop junctions with lower $1/f$ noise.
- Realize fully controllable three-qubit clusters within a generally scalable architecture.
- Develop switchable coupling between qubits.
- Realize systems of multiple qubits coupled through common harmonic oscillator buses – solid-state cavity QED.

- Demonstrate teleportation and rudimentary quantum error correction.
- Make first experimental tests of quantum algorithms with 3-5 qubits.

All of the above goals are among the priorities and can be achieved by European labs.

E. Long-term goals (2010 and beyond) (cf. also [2])

- Develop multi-qubit circuits (5-10 or more).
- Improve fidelity to the level needed for large-scale application.
- Develop interfaces to microwave and optical transmission lines.
- Develop interfaces for hybrid solutions to long term storage and communication.
- All of the above goals are among the priorities and can be achieved by European labs.

4.2.4 SEMICONDUCTOR QUANTUM DOTS

A. Physical approach and perspective

III-V Semiconductor heterostructures (e.g. GaAs, InP, InAs, etc) form the backbone of today's opto-electronics combining ultrafast electronics (e.g. HEMT), low-power optics together with the conversion between electronics and optics. The industrial development of this material class has also been fruitfully utilized in the field of QIPC. Employing nanofabrication and/or self-assembling techniques, quantum dots have been defined that can be addressed electrically and/or optically. The emerging field of quantum opto-electronics can provide an interface between solid state qubits and single-photon quantum optics.

Currently, quantum dot (QD) spin based quantum information processing (QIP) is pursued by 10 groups worldwide, 5 of which are located in Europe [L. Kouwenhoven (Delft, NL), K. Ensslin (ETH-Zurich, CH), G. Abstreiter (TU-Munich, DE), Ch. Bayer (Dortmund, DE) and A. Imamoglu (ETH-Zurich, CH)], as well as D. Loss (Basel, CH) on the theory side.

B. State of the art

The quantum dot qubits being developed in III-V semiconductors are based on the charge or spin properties of single electrons. Stable and reproducible quantum dots have been developed using split-gate techniques that can be loaded with exactly zero, one or two electrons. Electrical signals in the kHz to GHz range allow one to transfer reliably an individual electron from one quantum dot to another (Delft result). Circuits of such quantum dot devices form the basis for

the Loss-DiVincenzo proposal (Basel result) exploiting the electron spin as the qubit degree of freedom. In this scheme the electron charge is used for manipulation of the carriers. The spin dynamics is largely decoupled from the charge motion and remains coherent over long time scales. An important aspect of the Loss-DiVincenzo proposal is the full on-off control over the two-qubit interaction. In split-gate quantum dots this control via the spin-spin exchange interaction can be realized simply by switching electrical gate voltages. Charged qubits were also discussed by the Oxford group, and served as a model for early implementations of quantum logic gates.

The current status in the field is the realization of highly controllable quantum dots in various labs. (The material and nanofabrication flexibility is certainly strong in this QIPC approach.) The spin qubit states as well as the two qubit superposition states are easily resolved in transport measurements. An all-electrical readout of individual spins (e.g. single shot measurements) has been realized (Delft result). An ensemble average provides values for the spin life time of the order of milliseconds. It is important to note that these values are measured in an electrical circuit with all components activated and thus they include the effects from a realistic back-action (Delft result).

Quantum dots are often referred to as artificial atoms. Some of the fundamental atom-like properties of optically active quantum dots, such as photon antibunching and presence of absorption/emission lines predominantly broadened by radiative recombination, have already been confirmed experimentally. In contrast to atoms and electrically-defined quantum dots discussed earlier, optically active quantum dots suffer from spatial and spectral inhomogeneity; i.e. each quantum dot has an energy and location that is a priori impossible to be determined with reasonable accuracy. This property has important but not necessarily negative consequences for their applications in quantum information processing.

Arguably, the most successful application of quantum dots in quantum information processing has been the realization of high-efficiency single-photon sources (first results from Imamoglu et al., now at ETH Zurich). The fact that quantum dots exhibit no center-of-mass motion and that they can be embedded in nano-cavity structures with ultra-small mode volumes, enabled generation of a train of optical pulses that never contain more than a single photon, with efficiency exceeding 30%. In addition to potential applications in unconditionally secure quantum key distribution, such a source could also be used to produce indistinguishable single-photon pulses that form the backbone of linear optics quantum information processing schemes.

Cavity QED has been a central element in many quantum optics based quantum computation proposals. Recently, three groups have reported the observation of strong-coupling regime for a single quantum dot embedded in a nano-cavity structure (Würzburg result). While these experiments relied on a random spatial and spectral coincidence between the quantum dot and cavity modes, recent advances in growth and processing have demonstrated that it is possible to deterministically locate a single quantum dot at the anti-node of a photonic crystal nano-cavity structure which is

in turn spectrally resonant with the quantum dot exciton line (ETH Zurich result).

The progress in optical manipulation of quantum dot spins has been relatively slow. Deterministic charging of a single quantum dot with a single excess electron has been demonstrated by several groups. More recently, resonant laser transmission measurements on a single charged quantum dot have been used to demonstrate spin-selective optical absorption, or equivalently, Pauli-blocking of optical transitions (LMU and ETH-Zurich result).

C. Short-term goals (next 3-5 years)

- Integrate electrically controlled single-qubit gates, two-qubit gates and single-shot read-out into a single device
- Demonstrate optically controlled single- and two-qubit gates
- Realize coupling between two distant spins on a chip, via striplines or on-chip cavities
- Interconvert between single electron spins and single-photon polarization (standing qubit to flying qubit conversion)
- Develop the ability to measure and/or control the nuclear spin bath, in order to retrieve the intrinsically long electron spin coherence times
- Extend system size from two qubits to three
- Implement simple quantum algorithms, error correction protocols, etc.
- Explore and compare alternative semiconductor materials for quantum dots

D. Long-term goals (2010 and beyond)

- Develop multi-qubit circuits in a scalable architecture
- Improve fidelity to the level needed for fault tolerance
- Demonstrate a quantum repeater (photon to spin to photon conversion)

4.2.5 LINEAR OPTICS

A. Physical approach and perspective

Optical quantum computing (OQC) exploits measurement-based quantum computing schemes with photons as physical qubits. The interaction between separate photonic qubits is induced by measurement, as opposed to a direct interaction via nonlinear media. The two main physical architectures for OQC are based on proposals by Knill, Laflamme and Milburn [1], the KLM architecture, and by Raussendorf and Briegel [2], the one-way quantum computer with cluster states:

- KLM allows universal and scalable OQC using only single photons, linear optics and measurement. The by now seminal KLM work was based on the important findings of Gottesman, Chuang and Nielsen concerning the role of teleportation for universal quantum computing. The physical resources for universal (optical) quantum computation in the KLM scheme are multi-partite entangled states and (entangling) multi-particle projective measurements.
- Cluster state quantum computing has become an exciting alternative to existing proposals for quantum computing, and a linear optics approach is one possible implementation. It consists of a highly entangled multi-partite state called a cluster state, combined with single-qubit measurements and feed-forward, which are sufficient to implement scalable, universal quantum computation. Different algorithms only require a different “pattern” of single qubit operations on a sufficiently large cluster state. Since only single-particle projections, together with the ability to construct the initial highly entangled cluster state, are needed to operate such a one-way quantum computer, the cluster state approach might offer significant technological advantages over existing schemes for quantum computing: this includes reduced overall complexity and relaxed physical demands on the measurement process (as compared to sensitive multi-partite projections) as well as a more efficient use of physical resources.

Currently, the linear optics approach to quantum computation is pursued by the following European groups: K. Banaszek (Torun, PL), F. DeMartini (Rome, IT), N. Gisin (Geneva, CH), P. Grangier (Orsay, FR), A. Karlsson (Stockholm, SE), J. Rarity (Bristol, UK), A. Shields (Cambridge, UK), I. Walmsley (Oxford, UK), H. Weinfurter (Munich, DE), and A. Zeilinger (Vienna, AT).

B. State of the art

Important key elements for linear optics quantum computation, namely the generation of entangled states, quantum state teleportation and entanglement swapping have already been realized early in the field

(e.g. teleportation in 1997 and entanglement swapping in 1998). The latest developments include realization of entanglement purification, freely propagating teleported qubits and feed-forward technology.

Several practical designs implementing the KLM scheme have subsequently been developed. Experimental methods for ultra-precise photonic quantum state creation, which serve as ancillas in the measurement-based schemes, now achieve typical fidelities above 99%. Using coincident detection there have been a range of demonstrations of nondeterministic two-qubit gates: a fully-characterized two-photon gate operating with >90% fidelity, four-photon CNOT gates both with entangled ancilla and with teleportation, a KLM nonlinear sign shift gate and a three-photon simulation of the entangled-ancilla gate. These gates can be made scalable with additional resources. Several of these gates have been used in simple applications such as demonstrations of quantum error encoding and generalized non-destructive quantum measurement circuits of two classical logic gates and Bell measurement for teleportation.

Proposals for the optical implementation of cluster state quantum computing have been put forward recently and are promising significant reductions in physical resources by two orders of magnitude as compared to the original KLM scheme. Separately, a variety of modifications to KLM has been suggested to also reduce resource requirements. Recently, the realization of a photonic four-qubit cluster state allowed to demonstrate the feasibility of one-way quantum computing through a universal set of one- and two-qubit operations, as well as the implementation of Grover’s search algorithm [3].

Enabling technologies for OQC are:

- Characterization of photonic quantum states and processes. A complete, tomographic, characterization of individual devices is indispensable for error-correction and has quite progressed within the last years. Quantum process tomography can be used to fully characterize a quantum gate, probing it either with a range of input states or with a single bipartite maximally entangled state, the second method being the only viable one for continuous variable quantum processors. Based on the information gained from a complete process characterization it was recently shown how to estimate (and bound) the error probability per gate.
- Development of single photons and/or entangled photon sources is required for OQC. Currently, no source of timed single photons or entanglement is available. In the meantime, bright, albeit non-deterministic sources of correlated photons or entangled-photon pairs are critical to allow on-going evaluation of circuit technology as it is developed. Ultra bright and compact sources, some fiber-coupled to improve mode quality, have been developed. Relatively brighter sources (though not yet in absolute terms) have been demonstrated using periodically-poled nonlinear waveguides.

High-fidelity multi-qubit measurements (in the KLM scheme) and reliable preparation of multi-qubit states (in both the KLM and the cluster state scheme).

C. Strengths and weaknesses

Current drawbacks of the OQC approach are low photon creation rates, low photon detection efficiencies, and the difficulties with intermediate storage of photons in a quantum memory (see also section 4.1.3).

Advantages are obviously low decoherence (due to the photon's weak coupling to the environment), ultrafast processing, compatibility to fiber optics and integrated optics technologies and, in principle, straightforward scalability of resources. A major advantage for OQC is the very short time for one computational step achievable by using ultra-fast switches for the implementation of active feed-forward. With present technologies this can be done in less than 100 nanoseconds (in the future probably down to 10 nanoseconds). However, the low efficiencies quoted above are presently an important practical limitation to scalability, in the sense that they damp exponentially the success probability of most quantum operations.

D. Challenges

The main challenges for OQC can be summarized as follows:

- To achieve fault-tolerant quantum computing. The basic elements of fault-tolerance for OQC are becoming well understood. It has recently been shown that also optical cluster state QC may be performed in a fault-tolerant manner. Error models for KLM-style OQC have found that error thresholds for gates are above 1.78%.
- To reduce the resources required for OQC further and to find the limiting bounds on the required resources.
- To achieve massive parallelism of qubit processing by investing in source and detector technologies. Specifically, the development of high-flux sources of single photons and of entangled photons as well as photon-number resolving detectors will be of great benefit to achieve this goal.
- To realize fast optical switches for implementing active feed-forward. This is a crucial step towards deterministic linear-optics quantum computation.
- To generate high-fidelity, large multi-photon (or, more generally, many-particle) entangled states. This will be of crucial importance for cluster state quantum computing.
- To implement OQC architectures on smaller, integrated circuits. All of the current technologies involve either free space optics or combinations of free-space optics and optical fibers. To achieve long term scale-up, it will be essential to move to waveguide and integrated optics.

4.2.6 IMPURITY SPINS IN SOLIDS AND SINGLE MOLECULAR CLUSTERS

A. Physical approach and perspective

Storage and processing of information can be carried out using individual atomic and molecular spins in condensed matter. Systems falling into this category include dopant atoms in semiconductors like phosphorous or deep donors in silicon or color centers in diamond, nitrogen or phosphorus atoms in molecules like C60, rare earth ions in dielectric crystals and unpaired electrons at radiation induced defects or free radicals in molecular crystals. The main attraction of spins in low-temperature solids is that they can store quantum information for up to several thousand seconds [1]. Specific systems have been selected based on criteria like: dephasing time, optical access, single quantum state readout, and nanostructuring capabilities. While most of these systems are scalable in principle, technical progress in single quantum state readout, addressability and nanoengineering is necessary.

Another solid basis for quantum information processing, which relies on new molecules engineered with features suitable for qubit encoding and entanglement, is provided by Single Molecular Magnets (SMMs). Current research activity focuses on the control of the coherent spin dynamics in molecular spin clusters, which implies the control of decoherence mechanisms both at synthetic level and in terms of modelling. While most of the experiments are currently performed on bulk crystals, the final goal of manipulating single molecular spins is drawing increasing attention towards the grafting of molecules at surfaces and the development of techniques for readout.

Research groups engaged in QIP research regarding impurity spins in solids in Europe include A. Briggs (Oxford, UK), P. Grangier (Orsay, FR), O. Guillot-Noël and P. Goldner (Paris, FR), W. Harneit (Berlin, DE), S. Kröll (Lund, SE), J.L. LeGouët (Orsay, FR), M. Mehring (Stuttgart, DE), K. Mølmer (Aarhus, DK), J.F. Roch (Cachan, FR), M. Stoneham (London, UK), D. Suter (Dortmund, DE), J. Twamley (Maynooth, EI), J. Wrachtrup (Stuttgart, DE).

Research groups working on QIP with molecular spin clusters in Europe include D. Loss (Basel, CH), B. Barbara and W. Wernsdorfer (Grenoble, FR), M. Affronte and F. Troiani (Modena, IT), D. Gatteschi (Florence, IT), R. E. P. Winpenney and G. Timco (Manchester, UK).

B. State of the art

Impurity spins: Atomic and molecular spins in solids have received considerable attention as qubits. Already Kane's [1] proposal has underlined the basic challenges and opportunities of such systems in quantum computing. In the meantime a number of related

systems like dilute rare earth ions, color centers, random deep donors in silicon with optically controlled spin and defects in wide and narrow band gap semiconductors have underlined their potential usefulness in QIP [2]. Most approaches use electron or nuclear spin degrees of freedom as quantum bits. The specific advantages of spin systems includes long decoherence times [3] and access to highly advanced methods for precise manipulation of quantum states. The experimental techniques that have made liquid state NMR the most successful QIP technique in terms of precise manipulation of quantum states so far are currently being transferred to solid-state systems. These systems may be able to overcome the scalability problems that plague liquid state NMR while preserving many of the advantages of today's liquid state work.

In detail the following landmark results have been achieved:

1. Magnetic resonance on single defects detected by charge transport and single spin state measurements by optical techniques.
2. Single and two qubit quantum gates on single defect spins in diamond.
3. For rare earth crystals preparation and readout of ensemble qubit states Rabi flops of a qubit, and qubit decoherence times on the order of seconds have been achieved. State control and quantum state tomography with a fidelity > 90% was shown. Photon storage for more than one second has been shown.
4. The preparation of Bell states with electron and nuclear spin ensembles as well as a three qubit Deutsch-Jozsa algorithm has been achieved.
5. A scalable architecture has been developed for N@C60 on Si and decoherence times have been measured to be up to 1 s.

All of these are European achievements (point 3 was partly achieved in Australia).

SMMs: Quantum dynamics of spins in molecular clusters has been deeply studied by a number of fundamental works in the last decade. Decoherence and dephasing mechanisms have been investigated in assemblies: the intrinsic coherence times are expected to be longer than microseconds (preliminary experiments provide a lower bound of few tens of ns); similarly, the switching rates for one-qubit and two-qubit gates are estimated to be on the order of hundreds of picoseconds.

Recent important achievements are:

1. Proposals for the implementation of the Grover's algorithm in high spin SMMs [4], and of universal solid state quantum devices in antiferromagnetic spin clusters;
2. Synthesis of specific molecules providing promising test-beds for scalable schemes [5];
3. Entanglement of states belonging to different molecules inspired both synthesis of new molecular dimers and elaboration of specific quantum algorithms that exploit some features of molecular clusters.

All of these are European achievements.

C. Strengths and weaknesses

Impurity spins: The strength of defect center QIP in solids are the long decoherence times of spins even under ambient conditions and the precise state control. Depending on the system, electrical as well as optical single spin readout has been shown (fidelity of 80%). Substantial progress in the nanopositioning of single dopants with respect to control electrodes has been achieved. Weaknesses are: Electrical and optical readout of spin states has been shown up to now for only a single type of defect. Nanopositioning of defects is still a major challenge (which has seen dramatic progress for phosphorus in silicon). However there are schemes, based on deep donors in Si, where nanopositioning is not needed. Instead the randomness is exploited so as to make maximum use of spatial and spectral selection to isolate qubits and their interactions. Manipulation and readout is optical. The situation is similar for rare earth crystals, but in this case a fully scalable scheme still needs to be developed.

SMMs: The bottom-up approach used by supra-molecular chemistry offers simple and relatively cheap processes for the fabrication of quantum nanosized molecules exhibiting multi-functionality like the switchability of magnetic states with light, resonance at RF-MW radiation, etc. Moreover, the control on and the sharp definition of eigenstates and eigenvalues in magnetic molecules provides an extraordinary stimulus for the development of new quantum algorithms and schemes. In the latter case, the main issue would be to prove that single, isolated molecules behave not much differently from what is observed in experiments performed on assemblies of molecules.

D. Short-term goals (next 3-5 years)

Impurity spins: Impurity systems form a bridge for transferring quantum control techniques between atomic and solid state systems. Close interaction between the atomic physics and solid state communities is a key ingredient for achieving this.

- The mid term perspectives for phosphorus in silicon are the demonstration of single spin readout and two qubit operations. Major efforts are concentrated in the US and Australia.
- Optical readout of defects in diamond heads towards a three qubit system and demonstration of teleportation by 2006. For further scaling advanced nanoimplantation techniques need to be developed.
- For rare earth crystals the expected developments in the near future (1 year) includes the demonstration of two-qubit gates. Next, single ion readout will be developed for scaling up to several qubits.
- For N@C60, single readout for single spins should be demonstrated by 2006. For the scheme based on deep donors in Si or diamond, short term goals are demonstrations of all the key steps of fabrication, preparation, readout, and manipulation.

Excluding the first, all other goals are within reach of European laboratories.

SMMs: The main goals can be summarized as follows:

- To engineer new molecular clusters for the optimization of the coherent dynamics of spins, and design, synthesize and characterize controlled molecular linkers between spin clusters;
- To set up experiments for the direct observation of coherent dynamics (for instance Rabi oscillations, spin echo experiments), and probe, understand and reduce the intrinsic decoherence mechanisms in specific cluster qubits;
- To develop computational schemes exploiting the features of molecular cluster qubits, and study different functionalities (f.i. switchability) of molecules useful for specific tasks in complex architectures of QIP.

These goals are achievable by European laboratories.

E. Long-term goals (2010 and beyond)

For **impurity spins** the main long-term challenges are

- Coupling of defects in wide band gap semiconductors to an optical cavity mode. Implantation of defects with nm accuracy in registry with control electrodes. Improvement in optical detection efficiency by one order of magnitude to allow room temperature single-spin state read-out.
- For rare earth ions efforts should be joined with crystal growth research (inorganic chemistry) to create appropriate materials for larger scale systems. As an example subblocks of smaller number of qubits within a larger chain could be selectively activated for operations by electrodes spaced a few tens of nm on the crystal surface. It can be expected that quantum computing in RE crystals will both contribute to and benefit from the development and knowledge base in the rare earth crystal area in general.
- Few-qubit device could be built on the basis of N@C60 by integrating nanopositioning of

molecules with single-spin readout devices and control electronics.

- Few-qubit (up to perhaps 20 qubit) devices based on deep donors in silicon or silicon-compatible systems seem possible. Such devices should be linked into larger groups by flying qubits based largely on technology known from other fields. Achieving higher temperature is also of importance here.

For **SMMs**, the long-term challenges can be summarized as follows:

- Definition of reliable procedures for preparing, characterising and positioning (arrays of) molecular spin cluster qubits.
- Development of models and experimental methods for efficient read-out.

4.3 QUANTUM INFORMATION SCIENCE -THEORY

4.3.1 INTRODUCTION

The development of quantum information science (QIS) was initially driven by theoretical work of scientists working on the boundary between Physics, Computer Science, Mathematics, and Information Theory. In the early stages of the development of QIS, theoretical work has often been far ahead of experimental realization of these ideas. At the same time, theory has provided a number of proposals of how to implement basic ideas and concepts from quantum information in specific physical systems. These ideas are now forming the basis for successful experimental work in the laboratory, driving forward the development of tools that will form the basis for all future technologies which employ, control and manipulate matter and radiation at the quantum level.

Today one can observe a broad and growing spectrum of theoretical activities. Investigations include, to name just a few examples,

- basic concepts such as entanglement and decoherence,
- characterization and quantification of (two- & multi-party) entanglement,
- novel quantum algorithms and communication protocols,
- capacities of noisy quantum communication channels,
- optimization of protocols for quantum cryptography,
- new computer models and architectures.

Another important class of theoretical work is concerned with implementations of these abstract concepts in real physical systems.

In fact, many of these theoretical proposals have formed the starting point as well as the guide for experimental work in the laboratories, as is described in the other sections of this document. Last, but not least, the transfer of concepts from quantum information

theory to other fields of physics such as condensed matter physics or quantum field theory has proved fruitful and has attracted considerable interest recently.

It is important to realize that these activities are often interdisciplinary in nature and span a broad spectrum of research in which the different activities are benefiting from each other to a large degree. Thus it does not seem to be advisable to concentrate research on too narrowly defined topics only. Theory groups in Europe have been consistently delivered international leadership in the entire spectrum of research (see more below). This has been facilitated by a flexible and typically broad financing on European and national levels in the past.

In the following we give a brief outline of the current status and the perspectives of the main areas of quantum information theory.

4.3.2 QUANTUM ALGORITHMS & COMPLEXITY

Following Deutsch's fundamental work in 1985 that demonstrated the potential power of quantum algorithms and quantum computers, Shor demonstrated in 1994 that integers can be efficiently factorized on a quantum computer. Factoring is the task of decomposing an integer, say 15, into a product of prime numbers: $15=3*5$. Its importance is immense because many modern cryptographic protocols (for instance the famous RSA cryptosystem) are based on the fact that factoring large integers, as well as computing discrete logarithms, is a hard problem on a classical computer. Shor's result means that quantum computers could crack most classical public-key cryptosystems used at present. It has led to extensive work on developing new quantum algorithms. Progress has been made on the Hidden Subgroup problem (which generalizes Shor's algorithm) in the case of non-Abelian groups, like affine groups, the dihedral group, or solvable groups with small exponent. A quantum algorithm was discovered for finding solutions to Pell's equation, which is an important problem in algebraic number theory. Strong links have been established between known quantum algorithms and lattice problems. Finally Grover's quantum "data base" search algorithm allows a quantum computer to perform an unstructured search quadratically faster than any classical algorithm.

In parallel with the development of new quantum algorithms, new algorithmic techniques have been developed. Examples of these are adiabatic quantum computing which is a very versatile method of approaching virtually any computational task; and quantum random walks which have enabled important generalizations of Grover's search algorithm. There has also been considerable development of new protocols for quantum communication. The objective may be to carry out a task which is possible classically, but with significantly less communication, such as Quantum Fingerprinting or the Hidden Matching problem. Or it may be to realize tasks which are impossible classically such as biased Coin Tossing and Quantum Bit String Generation, Quantum String Commitment, resilient and unconditionally secure Digital Signatures, or Private Information Retrieval. The importance of these latter tasks lies in their application to "mistrustful cryptography", this is the field of cryptography dealing with the problem of two or more people who do not trust

each other, but must accomplish some goal together (for instance concluding a commercial deal, consulting a data base, etc.). We expect that the existing protocols will be improved and will gradually be implemented in the laboratory (as was recently the case for quantum bit string generation). We also expect the development of new protocols for quantum communication.

4.3.3 COMPUTATIONAL MODELS & ARCHITECTURES

There are many different ideas of how to make quantum systems compute. While these different computational models are typically equivalent in the sense that one can simulate the other with only polynomial overheads in resources, they may be quite different in practice, when it comes to a particular class of problems. They also suggest different procedures to achieve fault tolerant computation, many of them yet to be explored in detail. At the moment the main contenders of fundamental architectures are:

- The gate or circuit model (computation realized by series of elementary unitary transformations on a few qubits at a time).
- The one-way quantum computer (computation realized by sequence of 1-bit measurements on a pre-entangled cluster state).
- Adiabatic computing (computation realized by smoothly changing a Hamiltonian, whose ground state, at the end of the process, encodes the solution of the given problem).
- Quantum cellular automata (quantum version of classical cellular automata).
- Quantum Turing machine (quantum version of classical Turing machine).

Most recently, we have seen a series of theoretical work analyzing the connection between the different computational models. The benefit of these works lies in a better understanding of the capabilities and advantages of the individual models, and of the essential features of a quantum computer. In the future we expect that optimized models (i.e. taking the best

out of the different approaches) will be developed. We also expect that these models will have an increasing impact on (i) the formulation of new quantum algorithms and (ii) the evaluation of physical systems regarding their suitability for fault-tolerant quantum computation. Both of these points are of great importance for the field: While new algorithms will further enlarge the range of applications for quantum computers, new methods for fault-tolerant computation will hopefully make it technologically less challenging to realize scalable quantum computers in the laboratory.

4.3.4 GEOMETRIC AND TOPOLOGICAL METHODS FOR FAULT TOLERANT QUANTUM COMPUTING

An alternative approach to achieve fault-tolerant quantum computation is by geometric means. In this approach, quantum information is encoded in a set of energy degenerate states, depending on dynamically controllable parameters. Quantum gates are then enacted by driving the control parameters along suitable loops. These transformations, termed holonomies, are suitable to realize a set of universal quantum gates. Implementation schemes of geometrical computation have been proposed for several different physical systems, most notably for trapped ions.

Topological models for quantum computing have been also considered. In this case, the fault-tolerant properties are already built-in at the physical level and no active error detection and recovery is involved. Quantum encoding is performed in a degenerate ground state separated from the excited states by a finite energy gap; for low enough temperature, this implies an exponential suppression of leakage due to thermal fluctuations. Moreover, topological features can render such a ground state stable against errors acting locally in space. Robust quantum manipulations can be then enacted by winding anyonic excitations around each other and finally annihilating them back over the ground state.

The existing protocols for fault tolerant quantum computation have been specifically designed for phenomenological uncorrelated noise, while few results are known for a scenario with memory effects, i.e. non-

Markovian noise, arising from the Hamiltonian interaction with the environment. In particular this raises the question of fault tolerant schemes for phenomenological noise with memory.

4.3.5 QUANTUM SIMULATIONS

Quantum simulators may become the first application of quantum computers, since with modest requirements one may be able to perform simulations which are impossible with classical computers. At the beginning of the 80's it was realized that it will be impossible to predict and describe the properties of certain quantum systems using classical computers, since the number of variables that must be stored grows exponentially with the number of particles. A quantum system in which the interactions between the particles could be engineered would be able to simulate that system in a very efficient way. This would then allow, for example, studying the microscopic properties of interesting materials permitting free variation of system parameters. Potential outcomes would be to obtain an accurate description of chemical compounds and reactions, to gain deeper understanding of high temperature superconductivity, or to find out the reason why quarks are always confined.

A quantum simulator is a quantum system whose dynamics can be engineered such that it reproduces the behaviour of another physical system which one is interested to describe. In principle, a quantum computer would be an almost perfect quantum simulator since one can program it to undergo any desired quantum dynamics. However, a quantum computer is very difficult to build in practice and has very demanding requirements. Fortunately, there are physical systems with which it is not known how to build a quantum computer, but in which one can engineer certain kind of interactions and thus simulate other systems which so far are not well understood. This is due to the fact that with classical computers it is impossible to reproduce their dynamics, given that the number of parameters required to represent the corresponding state grows exponentially with the number of particles. Examples are atoms in optical lattices or trapped ions. In those systems, one does not require to individually address the qubits, or to perform quantum gates on arbitrary pairs of qubits, but rather on all of them at the same

time. Besides, one is interested in measuring physical properties (like magnetization, conductivity, etc.) which are robust with respect to the appearance of several errors (in a quantum computer without error correction, even a single error will destroy the computation). For example, to see whether a material is conducting or not one does not need to know with a high precision the corresponding conductivity. Molecular energies within chemical precision can also be computed by quantum simulations. Such computations are among the smallest applications of quantum computing. The use of 30 to 100 qubits for those algorithms exceeds the limitations of classical computing of molecular energies.

4.3.6 QUANTUM ERROR CORRECTION & PURIFICATION

The ability to carry out coherent quantum operation even in the presence of inevitable noise is a key requirement for quantum information processing. To cope with this decoherence problem, active strategies (quantum error correcting codes) as well as passive ones (error avoiding codes) have been developed.

Error correcting codes allow one to reduce errors by suitable encoding of logical qubits into larger systems. It has been shown that, with operations of accuracy above some threshold, the ideal quantum algorithms can be implemented. Recent ideas involving error correcting teleportation have made the threshold estimate more favorable by several orders of magnitude. This path has to be continued and adapted to realistic error models and to alternative models of quantum computation like the adiabatic model or the cluster model (see section 4.3.3).

In error avoiding codes, no active monitoring/intervention on the system is in principle necessary, since errors are simply circumvented. Error

avoiding is based on the symmetry structure of the system-environment interaction that in some circumstances allows for the existence of decoherence-free subspaces (DFS), i.e., subspaces of the system Hilbert state-space over which the dynamics is still unitary. The prototype noise model for which this situation occurs is provided by the so-called collective decoherence, where all the qubits are affected by the environment in the same way. For encoding a single logical noiseless qubit for general collective decoherence (dephasing), four (two) physical qubits are needed. DFSs have been experimentally demonstrated in a host of physical systems, and their scope extended by generalizing the idea of symmetry-aided protection to noiseless subsystems.

A fruitful connection with the theory of entanglement purification, which has been developed primarily in the context of quantum communication, and has been used in protocols such as the quantum repeater, is also emerging. Entanglement purification is a method to "distill" from a large ensemble of impure (low-fidelity) entangled states a smaller ensemble of pure (high-fidelity) entangled states. It seems that appropriately generalized procedures can be employed also in general quantum computation (e.g. for quantum gate purification, or for the generation of high fidelity resource states) while benefiting from the relaxed thresholds that exist for entanglement purification.

4.3.7 THEORY OF ENTANGLEMENT

Secret correlations are an important resource already in classical cryptography where, for perfect secrecy, sender and receiver hold two identical and therefore perfectly correlated code-books whose contents are only known to them. Such secret correlations can neither be created nor enhanced by public discussion. Entanglement represents a novel and particularly strong form of such secret correlations. Therefore, entanglement is a key resource in quantum information science. Its role as a resource becomes even clearer when one is considering a communication scenario between distant laboratories. Then, experimental capabilities are constrained to local operations and classical communication (LOCC) as opposed to general non-local quantum operations affecting both laboratories. This is an important setting in quantum communication but also distributed quantum computation and general quantum manipulations. The resulting theory of entanglement aims to answer three basic questions.

Firstly, we wish to characterize and verify entangled resources to be able to decide, ideally in an efficient way, when a particular state that has been created in an experimental set-up or a theoretical consideration contains the precious entanglement resource. For the experimental verification of this resource, the tool of entanglement witnesses allows to detect entanglement with local measurements only, and thus is easily implementable with present technology. Secondly, we wish to determine how entangled state may be manipulated under LOCC. In many situations an experimental setting will yield a certain type of entangled state that may suffer certain deficiencies. It may not be the correct type of state or it may have suffered errors due to experimental imperfections and be entangled. Once characterization methods have determined that the resulting state contains entanglement one can then aim to transform the initial state into the desired final state. Thirdly, it will be important to quantify the efficiency of all the processes and procedures as well as the entanglement resources that have been identified in the above two areas of research. If we have found entanglement in a state, then one will need to know how much of it there is.

Considerable progress in this area has been made in recent years, in particular in the case of bi-partite entanglement, but we are still far away from a comprehensive understanding of this key resource for quantum information processing. Research in this area will continue to play a central role in the field, and we expect that an increasing effort will be undertaken towards the classification and quantification of entanglement in multi-party entangled states. It is worth pointing out that insights in the theory of entanglement are not only important in the field of QIS itself, but they have now reached the stage where they are being applied to other areas of physics (see the subsection 4.3.10).

4.3.8 MULTI-PARTY ENTANGLEMENT & APPLICATIONS

Research on multi-particle entanglement is on the one hand expected to be focused on novel protocols for quantum information processing in the multi-partite setting. Entanglement in quantum systems embodying more than two constituents is fundamentally different from two-party entanglement, allowing for novel applications. This work on novel protocols includes work on instances of secret sharing or multi-partite fingerprinting. Notably, such multi-partite fingerprinting schemes would allow for the determination whether a number of databases are identical with little resources.

For quantum computation purposes it seems a major milestone to develop computation schemes that require minimal local control over interactions, such as in novel measurement-based computation schemes using multi-particle entangled resources as in cluster-state based approaches or in linear optics quantum computation. Alternatively, quantum cellular-automata based approaches may offer the potential of implementing quantum computation with little requirements of local control. Research work towards a complete understanding of the classification and quantification of multi-partite entanglement is expected to support such work, notably using methods from convex and global optimization, which give rise to novel methods for classification and quantification of entanglement. Laboratory quantum states such as random states or graph states as generalizations of cluster states may facilitate such studies.

On the other hand, there are good reasons to believe that a refined picture of criticality and phase transitions can be reached with the help of tools coming from the theory of entanglement. These ideas help in devising new simulation methods of ground states of many-body Hamiltonians in solid state physics (and many-body quantum systems in general). Finally, studies seem to indicate that questions in quantum field theory may become significantly more accessible using methods from entanglement theory (see also section 4.3.10).

4.3.9 NOISY COMMUNICATION CHANNELS

The proper understanding of the capacities of quantum communication channels is at the heart of the study of quantum communication tasks. Of particular importance are the transmission of classical or quantum information, or establishing secret keys. The general framework for distilling classical keys from quantum states have been also established, opening the possibility of secure communication on extremely noisy channels. But it is also known that one can use noise and perfect side communication to implement other cryptographic primitives like bit commitment and oblivious transfer. Channel capacities are of central interest in several different settings, being reflected notably by the classical capacity of quantum channels, quantum capacities, and entanglement-assisted capacities.

The central question is essentially what resources are required for transmitting classical or quantum information using quantum channels, such as optical fibers in a practical realization. An open problem is for example if entanglement can always be used as a source of secret keys; another key problem is whether an increased capacity can be obtained by employing entangled signal states (multiple uses) as opposed to single uses of the channel. This problem is widely known as the additivity problem for the Holevo capacity. There has been recent progress on this question, in particular linking this problem to seemingly unrelated additivity questions. In future work, this link between the different problems must be studied in more detail. For channels of salient interest this question will be directly addressed, using concepts of output purities. Novel methods from global optimization may be helpful here. For Gaussian channels, with practical importance in quantum communication with fibers, it seems within reach to find a complete answer to the above questions.

Finally, it is to be expected that more problems, as well as new perspectives, will arise when one considers multi-user channels, i.e., with more than one sender/receiver. While single-sender-receiver settings serve well to study bipartite correlations, such problems have an immediate impact on understanding multipartite correlations and their role in quantum communication via noisy channels. Also, quantum

analogues of certain basic classical network theory primitives have been identified, and the evidence for new non-classical features, such as negative partial information established. Further investigations will be needed to identify differences and similarities in the classical and quantum network theories.

4.3.10 FUNDAMENTAL QUANTUM MECHANICS AND DECOHERENCE

Quantum information was born, in part, via research on the famous Einstein-Podolski-Rosen paradox and the issue of quantum non-locality. In turn, quantum information led the discussion to move beyond purely qualitative aspects of non-locality to defining and investigating quantitative aspects. In particular, it is now understood that non-locality is one of the central aspects of quantum mechanics. More generally, quantum information profits substantially from studying the fundamental aspects of quantum mechanics and, at the same time, yields new points of view, raising hopes of gaining a deeper understanding of the very basis of quantum mechanics.

The study of decoherence is intertwined with the field of quantum information science in at least three ways. Key challenges of the next years in the study of decoherence with methods, tools and intuition from quantum information science will include the following:

- To understand the fundamental role of classical correlations and entanglement in the decoherence process itself, and to flesh out the robustness of entangled states under typical decoherence processes.
- To engineer further ways to prevent decoherence in applications of quantum information processing, by exploiting decoherence-free subspaces, entanglement

distillation, and dynamical decoupling procedures as bang-bang control.

- To support and contribute to experiments on decoherence to further understand the quantum to classical transition, and to determine what decoherence models are appropriate in what contexts.

4.3.11 SPIN-OFF TO OTHER FIELDS

A very exciting aspect of theoretical work in QIS is the impact that it is beginning to make on other fields of science. In the case of classical computing such insights include the first exponential bounds on certain locally decodable codes, classical proof systems for lattice problems, bounds on the query complexity of local search problems, an efficient classical cryptographic scheme whose security is based on quantum considerations, and a quantum method to compute how many Toffoli gates are required to realize a reversible classical computation. The potential that QIS is offering for classical computing and mathematics may be understood by the following analogy. Real analysis is a very successful discipline but it contained a number of unsolved problems that were only solved by considering complex numbers, i.e. going to a larger space in which to describe the problem. By analogy we expect that moving from classical state space into the much larger quantum mechanical state space we will find novel approaches towards the solution of problems that ostensibly lie entirely within the classical realm. As the enormous size of the quantum mechanical state space is due to entanglement, one may view this as a further consequence of entanglement and a further justification for the importance of the study of entanglement (see section 4.3.6).

Relatively recently the study of the role of entanglement in infinitely extended quantum many-body systems and quantum field theories has attracted considerable interest. Many of the questions that are now being asked in this area can only be answered or even formulated correctly because of the many insights and techniques gained in the research in entanglement theory in recent years. These results have already borne fruits in the development of novel simulation techniques for quantum many-body systems – generalization of the Density Matrix Renormalization Group (DMRG) method –, novel facets of correlations and phase transitions in spin systems and quantum field theories and solutions of longstanding open questions.

The entanglement between two systems cannot be shared with many others, a principle called 'monogamy': this leads to a fruitful relationship between entanglement theory and classical cryptography, and in particular between entanglement distillation and the classical key agreement scenario. Since the two schemes share similar objects, quantities and relations, it is expected that the parallel growth of these domains will lead to a deeper understanding of both of them.

This demonstrates that the research into entanglement, its characterization, manipulation and quantification will not only continue to have impact within quantum information but is now reaching the stage where its insights are being applied to other areas of physics, with potentially enormous benefits, both intellectually but perhaps also commercially.

4.3.12 EUROPEAN PERSPECTIVE

As shown in the examples above, quantum information science is a broad interdisciplinary effort whose key aim is to provide a theoretical basis for the control and exploitation of nature at the level of individual quanta. European research has played a leading role in its development and has established a strong set of world leading centers. The field is thriving and strongly expanding both by continuing enhancement of efforts in existing sub-areas but also through the innovation of new research directions.

A key area is the development of new approaches towards the realization of quantum information processing, both at the device dependent and independent level, as well as the concrete exploration of existing experiments that aim towards the practical implementation of quantum information processing. European researchers have made pioneering contributions to this area both on the theoretical level and, often in close collaboration, also experimentally. Major centers exist in various European countries (see below). These centers form the cores of a number of EU networks providing a level of interconnection on the European level.

Quantum information science has emerged from groundbreaking purely theoretical work and its major breakthroughs so far have generally been theory driven. This abstract work addresses entanglement theory, quantum algorithms, quantum communication and the applications of QIS to other fields such as condensed matter physics, field theory and the solution of problems in classical information theory by quantum methods. Researchers involve physicists, mathematicians, computer scientists and engineers demonstrating its strongly interdisciplinary character. Europe has made groundbreaking contributions to this area that has led the development of the field as a whole. It should be noted that the research landscape in these theoretical areas is still fluid and novel directions continue to emerge. A particular growth area is the application of the ideas emerging in QIS to other areas of physics,

mathematics and computer science, often providing entirely new problem solving techniques to existing areas. Intuitively this is due to the ability to access the full quantum mechanical state space rather than the much smaller classical state space which permits novel techniques to attack previously unsolved problems. Many new insights can be expected from this approach that will drive science forward in many areas.

Major centers exist in Austria, Belgium, Denmark, France, Germany, Netherlands, Poland, Spain, UK, and Switzerland. They have been linked through various EU project and the EU Network of Excellence QUIPROCONe as well as over the last five years through a European Science Foundation program on QIS addressing the need for this type of research for strong interconnections, the ability for informal collaborative visits to facilitate exchange of ideas. This is of particular importance in those aspects of theoretical research that are strongly interdisciplinary and where no single country possesses a critical mass of research.

Theoretical research in QIS in Europe has prospered through the efficient support for collaboration by the European Union, the European Science Foundation and the national funding bodies. In the face of growing international competition from North America, Japan and Australia it will be essential that flexible support compatible with innovative work will continue to be provided.

4.4 FUNDAMENTAL ISSUES ABOUT QIPC PHYSICS

QIPC relies on the manipulation and control of ensembles of qubits behaving according to the counter-intuitive laws of quantum physics. Most generally, though, quantum features are washed out in systems made of large numbers of particles. This decoherence phenomenon defines a kind of boundary between the microscopic world, where the quantum laws are dominant, and the macroscopic world, which behaves classically in spite of its underlying quantum nature. This boundary is fuzzy however. It largely reflects our lack of ability to isolate completely the system under study from its environment, made of a very big number of uncontrolled particles. By developing clever schemes, physicists and quantum information scientists are finding ways to fight this environment-induced decoherence. Some methods rely on the observation and manipulation of the environment itself, combined with feedback procedures counteracting the effects of decoherence on the system under study. Other methods, borrowing from the error correction schemes of classical computers, are at least in principle even more powerful. They are based on the redundant coding of the information in an ensemble of entangled qubits, monitoring the effects of decoherence on a subset of these qubits and applying correction procedures on others to restore the initial quantum state affected by decoherence. The progress towards the implementation of these methods, a prerequisite for large scale quantum computing to ever become feasible, is discussed in other parts of this report.

Here, we focus on other aspects of this field of research. The first is of a pedagogical nature. By attempting to “harness” the quantum laws and make

them useful to achieve logical tasks, QIPC scientists are, in some way, changing our view of the quantum-classical boundary. In the discussions of the founding fathers of quantum theory, this boundary was explored in thought experiments dealing with the principles of quantum measurements where microscopic systems are put in contact with macroscopic meters. Many QIPC experiments with atoms and photons can be viewed as modern realizations of these thought experiments. By doing them, physicists get more familiar with quantum concepts such as complementarity and wave particle duality. These experiments are now included in all modern textbooks of quantum physics. This pedagogical element must not be underestimated. The formation of an intuition for the quantum world is certainly an important ingredient in the education of students in physics and the study of QIPC is an excellent way to acquire this intuition. The students attracted by the esthetical qualities of this physics will be the researchers of tomorrow, who will apply their skills to QIPC or to other fields.

More fundamentally, these experiments also raise some issues at the forefront of physics. In QIPC, physicists learn to build systems of increasing size in quantum superposition, the Schrödinger cat states. This research is still in its infancy and many important issues remain to be explored, some of which are listed here non-exhaustively:

- **Size of mesoscopic superpositions.** This concept remains to be defined in a more quantitative way. Present experiments involve big molecules following spatially separated paths

in an interferometer, large numbers of photons stored in different states in boxes or propagating freely in laser beams and currents rotating in opposite directions in superconducting circuits. Large ensembles of atoms entangled with each other via their interaction with polarized laser beams share common features with these mesoscopic superpositions. Experiments with entangled Bose Einstein condensates of ultra cold atoms are also developing, completing this zoo of Schrödinger cat states. Clearly, the mass of the system (what about the photonic cat states?) or the number of particles involved (should we count the quarks in the molecular cat systems?) are not universal parameters to measure the magnitude of a given state superposition. Attempts to define a universal distance between the parts of the mesoscopic wave functions have been made and should be refined, to permit a meaningful comparison between experiments performed under very different conditions on disparate systems.

- **Non locality of mesoscopic superpositions.** Non locality has been investigated in great details so far on simple microscopic systems (pairs of photons or ions). It remains to be studied on larger systems. Mesoscopic objects made of many atoms or photons can now be built, in which the two parts of the wave function correspond to different locations in space, separated by a truly macroscopic distance. In the case of photons, this relies on the realization of some kind of non linear beam splitter device which, in a way very different from an ordinary beam splitter, collectively channels all the photons, at the same time, in one arm and in the other of an interferometer. Experiments with up to four photons have already been realized and non local cat states involving much larger photon numbers are in the making. Similar ideas are being developed to channel Bose Einstein condensed atoms collectively in different final positions. These systems combine the weirdness of the Schrödinger cat (large objects in state superpositions) and the strangeness of non locality. In simple two-particle systems, the amount of non-locality is measured by the degree of violation of Bell's inequalities. Versions of these inequalities for mesoscopic systems have been proposed. Testing them on large non local Schrödinger cat states remains to be done. The effect of decoherence on the violation of these mesoscopic versions of Bell's inequalities remains largely to be studied.
- **QIPC, gravitation and beyond.** In QIPC physics, the coupling to environment is considered to be electromagnetic. There is however another kind of environment against which no shielding exists, due to the gravitational field permeating all space. Decoherence induced by the fluctuations of gravitational waves of cosmological origin has been estimated theoretically. It is found to be negligibly small on atoms or molecules, and exceedingly efficient on large objects, for which it is by far more important than electromagnetic decoherence. The

transition appears to occur for objects of the order of Planck's mass (22 micrograms). Observing gravitational decoherence would be a daunting task, the challenge being to isolate effectively from electromagnetic influence objects made of many trillions of atoms. Experiments attempting to prepare quantum superpositions of states of a tiny mirror placed at the tip of a cantilever could be a first step in this direction. Even if gravitational effects are not of concern for QIPC applications, they are of a fundamental interest because they link the quantum-classical boundary to fundamental cosmological issues. Experiments on gravitational decoherence will not be realized in the near future, but thinking about them brings together scientists from quantum optics, mesoscopic physics, theoretical physics and cosmology. Deep questions such as the connection between information theory and black hole physics are also fruitfully debated, even though applications are not to be expected. Finally, these issues cannot be separated from a fundamental question about the future of quantum theory itself. Including gravitation into a comprehensive quantum framework has up to now eluded the efforts of theorists. A majority believes that such a comprehensive theory will retain the essential features of the present quantum theory, notably state superpositions and probabilistic behavior. Some however, who dislike the idea that "God is playing dice", hope that the new theory will reestablish some kind of classical determinism. There would then exist another kind of decoherence, more fundamental than the environment induced one. All attempts to build such theories so far have failed, but this does not deter their advocates. To test experimentally possible theories of this kind will be exceedingly difficult. It will imply, as a prerequisite, a very good control of the largely dominant environment induced decoherence. If a limitation to quantum laws as we know them were found at a given size scale, it would have tremendous consequences on our view of Nature, going far beyond the discussion about the feasibility of a quantum computer

APPENDIX A. QUANTUM INFORMATION TECHNOLOGIES

Even if the main thrust of the ongoing investigations in QIPC still belongs to basic research, one can already identify some of its areas that are closer to potential applications and even ready for commercial exploitation. In particular:

- **Quantum Communication** has already reached the market: two companies – the European idQuantique (<http://www.idQuantique.com>) and the US one MagiQ (<http://www.magiqtech.com>) – announced almost simultaneously the availability of a commercial quantum cryptography product. Other European companies developed commercial quantum key distribution scheme such as Elsig plc and SmartQuantum (<http://www.smartquantum.com>); moreover, in Japan major industrial players – NEC, Mitsubishi, Toshiba and NTT among others – started to allocate entire development teams to QKD systems (which did result in NEC and Mitsubishi already presenting working prototypes).
- **Quantum Computation** promises to deliver in the mid-term few-qubit quantum simulators which could be used to simulate the dynamics of complex systems (notice that a system with more than 30 qubits would be already beyond the reach of any foreseeable classical machine). Such few-qubit quantum computers will have also applications in quantum communication (as quantum repeaters), where they will be used to extend the working distances of quantum key distribution protocols beyond the current limitations.

- **Quantum Information Science – Theory** can also provide applications in the form of new classical simulation techniques for quantum many-body systems. Results from entanglement theory have in fact already led to fruitful generalizations of, e.g., the density matrix renormalization group method. The development of improved simulation techniques will lead to a deeper understanding of strongly correlated quantum systems (e.g., high-Tc superconductors, quantum magnets, etc.), which are of central interest in several areas of physics and that, in turn, will provide the basis for new technological applications.

Furthermore, a fresh look at QIPC from the broadest possible perspective also allows the identification of technologies that have gone past the proof-of-principle phase and are approaching the real world deployment stage. These **Quantum Information Technologies (QITs)** which are **designed to control and manipulate entanglement for (quantum) information processing and communication**, can be split into two main categories, being

- either technologies which represents genuine applications of QIPC (quantum information *enabled* technologies),
- or technologies which are needed for further advancing the field of QIPC (quantum information *enabling* technologies).

In what follows we detail the most promising technologies belonging to the first category, and the most needed ones as far as the second category is concerned

APPLICATIONS OF QIPC (QUANTUM ENABLED TECHNOLOGIES)

QUANTUM RANDOM NUMBER GENERATORS (QRNG)

Our information based society consumes lots of random numbers for a wide range of applications like, e.g., cryptography, PIN numbers, lotteries, numerical simulations, etc. The production of random numbers at high rates is technically challenging; at the same time, given the pervasiveness of the deployment of random numbers, poor random number generators can be economically very damaging.

Today, there are three kinds of random number generators on the market: computer-based pseudo-random number generators, discretised thermal noise and quantum based. The first kind produces sequences of numbers that look random, but are in fact the result of a deterministic process. The second kind is based on the complexity of thermal noise; however thermal relaxation times make these random number generators relatively slow, in the range of tens of Kbit/second.

On the other hand, quantum physics provides the only truly source of randomness in Nature. Moreover, in the basic configuration (a photon impinging on a beam

splitter followed by two detectors associated to the bit values 0 and 1) the origin of the randomness is clearly identified.

Today's commercial quantum random number generators produce about 4 Mbit/second. Their drawback is a significant cost compared to thermal noise based devices, but one expects that (near) future QRNG will provide higher rates at lower costs.

QUANTUM METROLOGY

Entangled states provide instances of objects that can be designed to be very robust to unwanted noise, while at the same time being extremely sensitive to a quantity we need to measure. This sensitivity can be exploited to overcome the classical limits of accuracy in various kinds of measurements, for example in ultra-high-precision spectroscopy, or in procedures such as positioning systems, ranging and clock synchronisation via the use of frequency-entangled pulses. For instance, in the latter case, picosecond resolution at 3 km distance has been attained. Large scale laser interferometers with kilometre arm lengths are currently

being built or started operating in Europe, the USA and Japan with the hope to achieve the first direct detection ever of gravitational waves and thus to open a new field of astronomy. For these detectors the classical sensitivity limit is a serious restriction. It is likely that for the first detection one will have to implement continuous variable entangled light beams in the two interferometer arms to overcome the classical limits. Scientists in Europe and Australia have recently demonstrated the required quantum noise reduction (through squeezing) of laser light at kilohertz frequencies.

State-of-the-art atom clocks developed in Europe have reached the level of accuracy limited by quantum noise of atoms. Entanglement of atoms in clocks may allow surpassing this limit by generation of spin squeezed states of atoms. Work towards this goal is going on in Europe and in the US. Single quantum particles can be used as nanoscopic probes of external fields. Along these lines, atomic-scale (up to few nanometers) resolution in the measurement of the spatial structure of an optical field via a single ion, as well as sub-shot-noise atomic magnetometry via spin squeezing and real-time feedback, have been already experimentally demonstrated. In addition, the quantum regime is being explored and applied also in the manipulation of nanomechanical devices like rods and cantilevers of nanometer size, currently under investigation as sensors for the detection of extremely small forces and displacements.

One of the main step in the development of quantum correlation and quantum entanglement tools was a practical design of ultra-bright sources of correlated photons and development of novel principles of entangled states engineering. This also includes entangled states of higher dimensionality and entangled quantum states demonstrating simultaneous entanglement in several pairs of quantum variables (hyper-entanglement), and calibration of single-photon detectors without any need for using traditional blackbody radiation sources. This unique possibility of self-referencing present in the optical system that is distributed in space-time is the main advantage of quantum correlation and entanglement. The fact that spontaneous parametric down-conversion (SPDC) is initiated by vacuum fluctuations serves as a universal and independent reference for measuring the optical radiation brightness (radiance). It gives the possibility of accurately measuring the infrared radiation brightness without the need of using very noisy and low sensitivity infrared detectors. Development of periodically poled nonlinear structures has opened the road for practical implementation of sources with high intensity of entangled-photon flux and with ultra high spectral

bandwidth for biomedical coherence imaging. Recent demonstrations have shown the possibilities for multi-photon interferometry beyond the classical limit. It has been shown that weak field homodyning could yield enhanced resolution in phase detection. First experimental implementations of quantum ellipsometry indicated the high potential of quantum polarisation measurement. The basic physical principles of optical coherence tomography with dispersion cancellation using frequency entangled photon pairs for sub-micron biomedical imaging have been demonstrated in model environments. The use of quantum correlations led to the design of a new technique for characterising chromatic dispersion in fibers. The intrinsically quantum interplay between the polarisation and frequency entanglement in CSPDC gave rise to a polarisation mode dispersion measurement technique that provides an order of magnitude enhancement in the resolution.

QUANTUM IMAGING

It is possible to generate quantum entanglement between the spatial degrees of freedom of light, an aspect which enables one to use quantum effects to record, process and store information in the different points of an optical image, and not only on the total intensity of light. One can then take advantage of a characteristic feature of optical imaging, which is its intrinsic parallelism. This opens the way to an ambitious goal, with a probable significant impact in a mid-term and far future: that of massively parallel quantum computing. In a shorter perspective, quantum techniques can be used to improve the sensitivity of measurements performed in images and to increase the optical resolution beyond the wavelength limit, not only at the single photon counting level, but also with macroscopic beams of light. This can be used in many applications where light is used as a tool to convey information in very delicate physical measurements, such as ultra-weak absorption spectroscopy, Atomic Force Microscopy etc. Detecting details in images smaller than the wavelength has obvious applications in the fields of microscopy, pattern recognition and segmentation in images, and optical data storage, where it is now envisioned to store bits on areas much smaller than the square of the wavelength. Furthermore, spatial entanglement leads to completely novel and fascinating effects, such as “ghost imaging”, in which the camera is illuminated by light which did not interact with the object to image, or “quantum microlithography”, where the quantum entanglement is able to affect matter at a scale smaller than the wavelength.

TECHNOLOGIES NEEDED TO ADVANCE QIPC (QUANTUM ENABLING TECHNOLOGIES)

QUANTUM INTERFACES

Quantum interfaces between quantum information carriers (quantum states of light) and quantum information storage and processors (atoms, ions, solid state) are required as essential parts of a full-scale quantum information system. Such interfaces should thus be developed for connecting quantum computers

in small networks, or more generally for quantum communication purposes.

Let us first contrast the quantum technology required here to its classical counterpart. In classical optical communication, information is transferred encoded in pulses of light, which are possibly amplified, and then detected by photo detectors, transformed into electrical current pulses, amplified by electronics, and sent to

computers, phones, etc. This transformation of light into electrical signals forms a classical light-matter interface. But in quantum information processing, classical amplification or detection of light is inadequate, because it destroys the quantum state by adding extra noise to it. Hence a quantum interface has to be developed, in order to transfer the quantum state of light qubits (or light continuous variables) to or from atomic qubits (or atomic continuous variables). Quantum interfaces usually involve storage elements (quantum memories), and processing elements (deterministic or conditional quantum gates). They often involve also long-distance quantum teleportation of long lived atomic states, which allow for communication and quantum secret sharing tasks. Such long lived entanglement shared over a long distance requires transfer of entanglement from light (the long distance carrier) to atoms (the long lived objects), realized by the quantum interface. Many different quantum technologies can be used to implement the interfaces, e.g. atomic ensembles, cavity QED, solid state devices, etc.

HERALDED ENTANGLED PHOTON-PAIR SOURCES

Point to point earth based quantum communication is limited in distance by the losses of optical fibers. For long distance quantum communication (>500km) protocols with quantum repeaters are needed. Such schemes require, among other things, high quality sources of pairs of entangled photon, either on demand or heralded. Today's sources are probabilistic, based on spontaneous parametric down conversion. Future sources should keep or improve on the optical quality of the existing ones (compatible with single-mode optical fibers, Fourier-transform limited, and coherence length of several centimetres), provide larger rates and yields (probability of a photon pairs) while reducing the probability of multi-pairs.

The exact type of entanglement is not essential, but should involve two photons, one in each of two quantum channels (i.e. the entanglement obtained by bunching two single photons on a beam splitter is not

appropriate). At least one of the photons should be at the telecom wavelength around 1.55 microns. Depending on the protocol, the second photon can be around the same wavelength or at a shorter one, below one micron (but one should bear in mind that future progress in quantum communication protocols may affect the required specifications).

CHIP TRAPS FOR QUANTUM COMPUTING

The DiVincenzo criteria for quantum computing are currently approached from different directions. To date, ion traps offer the possibility to precisely manipulate and read out single qubits and to perform entangling gate operations, while the size of the system is currently limited to a few qubits. In contrast, with neutral atoms large ensembles of entangled qubits have been created while the manipulation of single atoms and their detection present a major challenge. Both these approaches – bottom up for ions and top down for atoms – need to be further developed to take quantum computation the next scale. Chip technology for trapping ions or neutral atoms will play a major role in this development.

For neutral atoms, chip traps offer precise positioning that enables controlled interactions and detection of single atom states. The first on-chip implementation of a high-finesse fibre resonator has very recently been demonstrated, offering at the same time a tool for manipulation, entanglement and detection of ions. In addition, this should be used in the future to establish an interface between stationary (atoms) and flying qubits (photons).

For ions, the chip traps serve to increase the number of qubits that can be handled. The segmentation of trap electrodes in microscopic traps allows for a multitude of miniature ion traps on one chip. Future developments have to meet two major challenges: finding a trap technology that features small heating rates and long coherence times, and a trap design that allows for transport of the ions (along with their contained quantum information) between all miniature traps on the chip. An integration of optical cavities as demonstrated for neutral atoms would be desirable, too.
